Digital Edition

WILEY Blackwell

Thomas' Hematopoietic Cell Transplantation

This book is dedicated to our patients and their families whose courage and trust enabled them to choose a difficult, dangerous, and sometimes unproven therapy which offered the only chance in their fight against a fatal disease. Today, many thousands of patients are alive after a successful hematopoietic cell transplantation, which would have been impossible without the fortitude of our patients, who took risks and thereby paved the way for the increasing application of this therapy. The progress in the area of clinical transplantation of hematopoietic cells would not have been possible without the dedicated, tireless work of the nurses and the supporting staff in the many transplant units around the world.

Thomas' Hematopoietic Cell Transplantation

Stem Cell Transplantation

VOLUME I

Edited by

Stephen J. Forman, MD
Chair, Department of Hematology and Hematopoietic Cell Transplantation
City of Hope Comprehensive Cancer Center
Duarte, CA, USA

Robert S. Negrin, MD
Professor of Medicine
Chief, Division of Blood and Marrow Transplantation
Stanford University
Stanford, CA, USA

Joseph H. Antin, MD
Professor of Medicine, Harvard Medical School
Chief, Stem Cell Transplantation
Dana-Farber Cancer Institute, Brigham and Women's Hospital
Boston, MA, USA

Frederick R. Appelbaum, MD
Member and Director, Clinical Research Division
Fred Hutchinson Cancer Research Center
Professor and Head, Division of Medical Oncology
University of Washington School of Medicine
Seattle, WA, USA

Fifth Edition

WILEY Blackwell

This edition first published 1994 © 1994, 1999, 2004, 2009, 2016 by John Wiley & Sons, Ltd.

This book comes with free access to a **Wiley Companion Digital Edition** powered by **VitalSource** providing a digital, interactive version of this book. Your Wiley Companion Digital Edition allows you to search, make notes and highlights, organize, clip figures, and link content.

To access your **Wiley Companion Digital Edition**
- Find the redemption code by carefully scratching away the top coating of the label found in the inside panel of the front cover of this book.
- Visit https://support.vitalsource.com for directions on how to first download the Vital Source Bookshelf to your device, computer or laptop, and then redeem your code. See support topic 'Getting Started with VitalSource Bookshelf'.

If you have purchased this title as an e-book, Wiley Customer Care will provide your access code for the online edition. Please visit http://support.wiley.com to request via the "Live Chat" or "Ask A Question" tabs within 90 days of purchase, and please have your receipt for verification.

Contents

Contributors, xi

Preface to the First Edition, xvii

Preface to the Fifth Edition, xviii

Tribute, xix

List of Abbreviations, xxii

VOLUME I

Section 1: History and Use of Hematopoietic Cell Transplantation

1 A History of Allogeneic and Autologous Hematopoietic Cell Transplantation, 1
Karl G. Blume and E. Donnall Thomas

2 Uses and Growth of Hematopoietic Cell Transplantation, 8
Mary M. Horowitz

Section 2: Scientific Basis or Hematopoietic Cell Transplantation

Section 2A: Hematopoiesis and Stem Biology Transplantation

3 Generation of Definitive Engraftable Hematopoietic Stem Cells from Human Pluripotent Stem Cells, 16
Laurence Dahéron and David T. Scadden

4 Hematopoietic Stem Cells, Regenerative Medicine, and Leukemogenesis, 25
Irving Weissman

5 Marrow Microenvironment and Biology of Mobilization of Stem Cells, 50
Michael P. Rettig, Mark A. Schroeder and John F. DiPersio

6 Expansion of Human Hematopoietic Stem Cells, 62
Colleen Delaney

7 Mesenchymal Stromal Cells and Hematopoietic Cell Transplantation, 69
Edwin M. Horwitz

8 Genetic Manipulation of Hematopoietic Stem Cells, 78
Jennifer E. Adair, Grant D. Trobridge and Hans-Peter Kiem

Section 2B: Immunology

9 Overview of Hematopoietic Cell Transplantation Immunology, 96
Paul J. Martin and Warren D. Shlomchik

10 Histocompatibility, 112
Effie W. Petersdorf

11 Natural Killer Cells and Allogeneic Hematopoietic Cell Transplantation, 126
Michael R. Verneris and Jeffrey S. Miller

12 Mechanisms of Tolerance, 136
Defu Zeng and Samuel Strober

13 The Pathophysiology of Graft-versus-Host Disease, 146
James L.M. Ferrara and Joseph H. Antin

14 Immune Regulation in Hematopoietic Cell Transplantation, 153
Robert S. Negrin and Jerome Ritz

15 Immune Reconstitution Following Hematopoietic Cell Transplantation, 160
Jarrod A. Dudakov, Miguel-Angel Perales and Marcel R.M. van den Brink

16 Biology of the Human Graft-versus-Tumor Response and How to Exploit It, 166
Edus H. Warren

17 Dendritic Cells in Hematopoietic Cell Transplantation, 178
Miriam Merad and Edgar G. Engleman

18 The Experimental Basis for Hematopoietic Cell Transplantation for Autoimmune Diseases, 191
Judith A. Shizuru

Section 2C: Technical Aspects

19 Pharmacologic Basis for High-dose Chemotherapy, 211
Borje S. Andersson, Benigno C. Valdez and Roy B. Jones

20 High-dose Preparatory Regimens, 223
William I. Bensinger

21 Reduced-intensity Allogeneic Transplantation Regimens, 232
Brenda M. Sandmaier and Rainer Storb

22 Radiotherapeutic Principles of Hematopoietic Cell Transplantation, 244
Jeffrey Y.C. Wong and Timothy Schultheiss

23 Radioimmunotherapy and Hematopoietic Cell Transplantation, 258
John M. Pagel and Ajay K. Gopal

24 Documentation of Engraftment and Characterization of Chimerism After Hematopoietic Cell Transplantation, 272
Paul J. Martin

25 The Detection and Significance of Minimal Residual Disease, 281
Merav Bar and Jerald P. Radich

26 Pathology of Hematopoietic Cell Transplantation, 292
Keith R. Loeb, Cecilia C. Yeung and Howard M. Shulman

27 Biostatistical Methods in Hematopoietic Cell Transplantation, 329
Joycelynne M. Palmer and Ted A. Gooley

28 Outcomes Research in Hematopoietic Cell Transplantation, 341
Stephanie J. Lee

Section 3: Patient-oriented Issues in Hematopoietic Cell Transplantation

29 The Evaluation and Counseling of Candidates for Hematopoietic Cell Transplantation, 349
Bart L. Scott and Brenda M. Sandmaier

30 Nursing Role in Hematopoietic Cell Transplantation, 362
Rosemary C. Ford, Mihkaila M. Wickline and Diane Heye

31 Ethical Issues in Hematopoietic Cell Transplantation, 374
David S. Snyder

32 Psychosocial Issues in Hematopoietic Cell Transplantation, 384
Richard P. McQuellon and Katharine E. Duckworth

33 Assessment of Quality of Life in Hematopoietic Cell Transplantation Recipients, 392
Karen L. Syrjala and Samantha Burns Artherholt

34 Sexuality Following Hematopoietic Cell Transplantation, 399
D. Kathryn Tierney

35 Hematopoietic Cell Transplantation: The Patient's Perspective, 407
Susan K. Stewart

Section 4: Sources of Hematopoietic Cell for Hematopoietic Cell Transplantation

36 Hematopoietic Cell Procurement, Processing, and Transplantation: Standards, Accreditation, and Regulation, 414
Phyllis I. Warkentin and Elizabeth J. Shpall

37 Bone Marrow and Peripheral Blood Cell Donors and Donor Registries, 423
Dennis L. Confer, John P. Miller and Jeffrey W. Chell

38 The Role of the Transplant Program in a Nuclear Accident or Terrorism, 431
Nelson J. Chao and Dennis L. Confer

39 Cord Blood Hematopoietic Cell Transplantation, 437
Hal E. Broxmeyer, Sherif S. Farag and Vanderson Rocha

40 Mobilization of Peripheral Blood Hematopoietic Cells for Autologous HCT, 452
Thomas C. Shea and John F. DiPersio

41 Peripheral Blood Hematopoietic Cells for Allogeneic Transplantation, 460
Norbert Schmitz and Peter Dreger

42 Cryopreservation of Hematopoietic Cells, 469
Scott D. Rowley

43 Use of Recombinant Growth Factors after Hematopoietic Cell Transplantation, 480
Jürgen Finke and Roland Mertelsmann

44 Hematopoietic Cell Transplantation from Human Leukocyte Antigen Partially Matched Related Donors, 489
Claudio Anasetti, Franco Aversa and Andrea Velardi

45 Hematopoietic Cell Transplantation from Unrelated Donors, 505
Effie W. Petersdorf

Section 5: Hematopoietic Cell Transplantation for Acquired Disease

46 Hematopoietic Cell Transplantation for Aplastic Anemia, 517
George E. Georges and Rainer Storb

47 Hematopoietic Cell Transplantation for Paroxysmal Nocturnal Hemoglobinuria, 537
Ryotaro Nakamura

48 Hematopoietic Stem Cell Transplantation for Chronic Myeloid Leukemia, 545
Jerald P. Radich and Ravi Bhatia

49 Hematopoietic Cell Transplantation for Juvenile Myelomonocytic Leukemia, 554
Charlotte M. Niemeyer and Franco Locatelli

50 Hematopoietic Cell Transplantation for Adult Acute Myeloid Leukemia, 563
Frederick R. Appelbaum

51 Hematopoietic Cell Transplantation for Childhood Acute Myeloid Leukemia, 576
Michael A. Pulsipher, Meghann McManus and Soheil Meshinchi

52 Hematopoietic Cell Transplantation for Acute Lymphoblastic Leukemia in Adults, 588
Stephen J. Forman

53 Hematopoietic Cell Transplantation for Acute Lymphoblastic Leukemia in Children, 600
Parinda A. Mehta and Stella M. Davies

54 Hematopoietic Cell Transplantation for Myelodysplastic Syndromes and Myeloproliferative Neoplasms, 613
H. Joachim Deeg

55 Hematopoietic Cell Transplantation for Multiple Myeloma, 625
Amrita Krishnan and Sergio A. Giralt

Index, 637

VOLUME II

56 Hematopoietic Cell Transplantation for Hodgkin Disease, 675
Philip J. Bierman and Auayporn Nademanee

57 Hematopoietic Cell Transplantation for Non-Hodgkin Lymphoma (B Cell), 692
Leslie L. Popplewell and Ginna G. Laport

58 Hematopoietic Cell Transplantation for Non-Hodgkin Lymphoma (T Cell), 703
Jasmine Zain and Sandra H. Thomas

59 Hematopoietic Cell Transplantation for Chronic Lymphocytic Leukemia, 714
Aaron C. Logan and David B. Miklos

60 Autologous Hematopoietic Cell Transplantation for Systemic Light Chain (AL-) Amyloidosis, 724
Heather J. Landau, Morie A. Gertz and Raymond L. Comenzo

61 Autologous Hematopoietic Cell Transplantation for Breast Cancer and Germ-cell Tumors, 739
Yago Nieto and Elizabeth J. Shpall

62 Hematopoietic Cell Transplantation for Renal Cell Carcinoma and Other Solid Tumors, 748
Richard W. Childs and Ramaprasad Srinivasan

63 Hematopoietic Cell Transplantation for Neuroblastoma, 760
Justin T. Wahlstrom and Katherine K. Matthay

64 Hematopoietic Cell Transplantation for Other Pediatric Solid Tumors, 768
Masanori Hayashi, David M. Loeb and Allen R. Chen

65 Hematopoietic Cell Therapy for Human Immunodeficiency Virus Infection, 781
Amrita Krishnan, Joseph Alvarnas, John J. Rossi and John A. Zaia

66 Hematopoietic Cell Transplantation for Autoimmune Diseases, 792
Richard A. Nash

67 Hematopoietic Cell Transplantation for Rare Hematologic Malignancies, 804
Vinod Pullarkat and Stephen J. Forman

68 Adoptive T-cell Therapy for Viral Disease in the Setting of Hematopoietic Cell Transplantation, 816
Catherine M. Bollard and Helen E. Heslop

69 Adoptive T-cell Therapy for Malignancy in the Setting of Hematopoietic Cell Transplantation, 826
Stephen J. Forman, Michael Kalos and Carl H. June

70 Relapse of Hematologic Malignancy After Allogeneic Hematopoietic Transplantation, 836
Richard Champlin

Section 6: Hematopoietic Cell Transplantation for Inherited Disease

71 Hematopoietic Cell Transplantation for Thalassemia, 842
Guido Lucarelli and Javid Gaziev

72 Hematopoietic Cell Transplantation for Sickle Cell Disease, 853
Mark C. Walters

73 Hematopoietic Cell Transplantation for Immunodeficiency Diseases, 866
Richard J. O'Reilly and Wilhelm Friedrich

74 Hematopoietic Cell Transplantation for Storage Diseases, 885
Joseph Rosenthal

75 Hematopoietic Cell Transplantation for Macrophage, Granulocyte and Osteoclast Disorders, 910
Rajni Agarwal

76 Hematopoietic Cell Transplantation for Fanconi Anemia, 923
John E. Wagner, Jakub Tolar, Arleen D. Auerbach and Margaret L. MacMillan

Section 7: Complications of Hematopoietic Cell Transplantation

77 Mechanisms and Treatment of Graft Failure, 944
Robert Lowsky and Hans Messner

78 Blood Group Incompatibilities and Hemolytic Complications of Hematopoietic Cell Transplantation, 955
Margaret R. O'Donnell

79 Principles of Transfusion Support Before and After Hematopoietic Cell Transplantation, 961
Jeffrey McCullough

80 Vascular Access and Complications, 976
I. Benjamin Paz

81 Pharmacologic Prevention of Acute Graft-versus-Host Disease, 990
Nelson J. Chao

82 T-cell Depletion to Prevent Graft-versus-Host Disease, 1004
Robert J. Soiffer

83 Manifestations and Treatment of Acute Graft-versus-Host Disease, 1012
Corey Cutler and Joseph H. Antin

84 Chronic Graft-versus-Host Disease – Clinical Manifestations and Therapy, 1020
Paul A. Carpenter, Mary E.D. Flowers and Steven Z. Pavletic

85 Bacterial Infections, 1038
Helen L. Leather and John R. Wingard

86 Fungal Infections After Hematopoietic Cell Transplantation, 1057
Kieren A. Marr

87 Cytomegalovirus Infection, 1069
John A. Zaia

88 Herpes Simplex Virus Infections, 1078
Sanjeet S. Dadwal and James I. Ito

89 Varicella Zoster Virus Infections, 1085
Dora Y. Ho and Ann M. Arvin

90 Epstein–Barr Virus Infection, 1105
Jennifer A. Kanakry and Richard F. Ambinder

91 Respiratory Viruses After Hematopoietic Cell Transplantation, 1112
Sachiko Seo and Michael Boeckh

92 HHV-6A, HHV-6B, HHV-7, and HHV-8 After Hematopoietic Cell Transplantation, 1122
Per Ljungman, Tetsushi Yoshikawa and Katherine N. Ward

93 Human Adenovirus, Polyomavirus, and Parvovirus Infections in Patients Undergoing Hematopoietic Stem Cell Transplantation, 1129
Hans H. Hirsch and Steven A. Pergam

94 Gastrointestinal and Hepatic Complications, 1140
David M. Hockenbery, Simone I. Strasser and George B. McDonald

95 Lung Injury Following Hematopoietic Cell Transplantation, 1156
Kenneth R. Cooke and Gregory A. Yanik

96 Kidney and Bladder Complications of Hematopoietic Cell Transplantation, 1170
Sangeeta Hingorani

97 Endocrine Complications Following Hematopoietic Cell Transplantation, 1181
Fouad R. Kandeel and Behrouz Salehian

98 Common Potential Drug Interactions Following Hematopoietic Cell Transplantation, 1206
Anne Poon and Lowan K. Ly

99 Nutrition Support of the Hematopoietic Cell Transplant Recipient, 1216
Paula Charuhas Macris and Kerry K. McMillen

100 Pain Management, 1225
Noelle V. Frey and Jonathan R. Gavrin

101 Oral Complications of Hematopoietic Cell Transplantation, 1242
Mark M. Schubert, Maria Elvira Pizzigatti Correa and Douglas E. Peterson

102 Growth and Development After Hematopoietic Cell Transplantation, 1257
K. Scott Baker and Anna Petryk

103 Delayed Non-malignant Complications After Hematopoietic Cell Transplantation, 1266
Smita Bhatia

104 Subsequent Malignant Neoplasms After Hematopoietic Cell Transplantation, 1275
Smita Bhatia and Ravi Bhatia

105 Neurologic Complications of Hematopoietic Cell Transplantation, 1287
Harry Openshaw and Bihong T. Chen

106 Vaccination of Allogeneic and Autologous Hematopoietic Cell Recipients, 1297
Trudy N. Small

Index, 1305

Associate Clinical Professor,
Department of Radiology,
City of Hope National Medical Center,
Duarte, CA, USA

Richard W. Childs, MD
Clinical Director,
NHLBI; Senior Investigator,
National Heart, Lung and Blood Institute,
National Institutes of Health, Bethesda, MD, USA

Raymond L. Comenzo, MD
Professor of Medicine and Pathology,
Tufts University School of Medicine; Attending
Physician and Director of the Transfusion Service
and the Cell Therapy Center,
Division of Hematology–Oncology,
Department of Medicine, Tufts Medical Center,
Boston, MA, USA

Dennis L. Confer, MD
Clinical Professor of Medicine,
Department of Medicine,
University of Minnesota; Chief Medical Officer,
National Marrow Donor Program,
Minneapolis, MN, USA

Kenneth R. Cooke, MD
Professor of Oncology and Pediatrics (PAR),
Division of Pediatric Hematology/Oncology,
Department of Oncology, Blood and Marrow
Transplant Program, Johns Hopkins University School
of Medicine, Baltimore, MD, USA

Maria Elvira Pizzigatti Correa, DDS, PhD
Professor of Oral Diagnosis,
Piracicaba School of Dentistry;
Dentist,
Hematology and Blood Transfusion Center,
Hemocentro, University of Campinas, UNICAMP,
Campinas, SP, Brazil

Corey Cutler, MD, MPH, FRCP(C)
Associate Professor of Medicine,
Harvard Medical School, Dana-Farber Cancer Institute,
Boston, MA, USA

Sanjeet S. Dadwal, MD
Associate Clinical Professor,
Division of Infectious Disease,
City of Hope National Medical Center,
Duarte, CA, USA

Laurence Dahéron, PhD
Head, iPS core facility,
Harvard Stem Cell Institute, Harvard University,
Boston, MA, USA

Stella M. Davies, MBBS, MRCP, PhD
Professor,
Division of Bone Marrow Transplantation and Immune
Deficiency, Cancer and Blood Diseases Institute,
Cincinnati Children's Hospital Medical Center,
Cincinnati, OH, USA

H. Joachim Deeg, MD
Professor of Medicine; Member,
Clinical Research Division, Fred Hutchinson Cancer
Research Center, University of Washington
Seattle, WA, USA

Colleen Delaney, MD, MSc
Director, Program in Cord Blood Transplantation
Associate Member, Clinical Research Division,
Fred Hutchinson Cancer Research Center
Associate Professor, Department of Pediatrics,
University of Washington School of Medicine,
Seattle, WA, USA

John F. DiPersio, MD, PhD
Professor of Medicine and Pathology and Immunology,
Deputy Director,
Siteman Cancer Center, Washington University School
of Medicine, St. Louis, MO, USA

Peter Dreger, MD
Professor of Medicine;
Head, Stem Cell Transplantation Unit,
Department of Internal Medicine V, University of
Heidelberg, Im Neuenheimer Feld 410,
Heidelberg, Germany

Katharine E. Duckworth, PhD
Assistant Professor,
Department of Medicine, Hematology, and Oncology,
Wake Forest Baptist Health, Comprehensive Cancer
Center of Wake Forest University,
Winston-Salem, NC, USA

Jarrod A. Dudakov, PhD
Senior Research Scientist,
Immunology Program, Memorial Sloan-Kettering
Cancer Center, New York, USA;
Department of Anatomy and Developmental Biology,
Monash University, Melbourne, Australia

Edgar G. Engleman, MD
Professor of Pathology and Medicine,
Stanford University School of Medicine;
Director, Stanford Blood Center,
Stanford, CA, USA

Sherif S. Farag, MD, PhD, MBBS
Lawrence H. Einhorn Professor of Oncology,
Department of Medicine, Indiana University School
of Medicine, Indianapolis, IN, USA

James L.M. Ferrara, MD, DSc
Professor of Cancer Medicine and Director,
Hematologic Malignancies Translational Research
Center, Tisch Cancer Institute,
Icahn School of Medicine at Mount Sinai,
New York, NY, USA

Jürgen Finke, MD
Professor,
Section of Allogeneic Stem Cell Transplantation,
Department of Internal Medicine I, Hematology,
Oncology and Stem Cell Transplantation,
Freiburg University Medical Center,
Freiburg im Breisgau, Germany

Mary E.D. Flowers, MD
Member,
Clinical Research Division, Fred Hutchinson Cancer
Research Center; Professor of Medicine, Department
of Medicine, University of Washington School of
Medicine, Seattle, WA, USA

Rosemary C. Ford, BA, BSN, OCN
Manager,
Transplant Clinic, Seattle Cancer Care Alliance,
Fred Hutchinson Cancer Research Center,
Seattle, WA, USA

Stephen J. Forman, MD
Chair,
Division of Hematology and Hematopoietic Cell
Transplantation, City of Hope Comprehensive Cancer
Center, Duarte, CA, USA

Noelle V. Frey, MD
Instructor of Medicine,
Division of Hematology–Oncology, Abramson Cancer
Center, University of Pennsylvania,
Philadelphia, PA, USA

Wilhelm Friedrich, MD
Professor of Pediatrics,
Department of Pediatrics, University Children's
Hospital Ulm, University of Ulm, Ulm, Germany

Jonathan R. Gavrin, MD
Clinical Professor,
Department of Anesthesiology and Critical Care,
Hospital of the University of Pennsylvania, Perelman
School of Medicine, Philadelphia, PA, USA

Javid Gaziev, MD, PhD, DMSc
Clinical Director,
International Center for Transplantation in Thalassemia
and Sickle Cell Anemia, Mediterranean Institute of
Hematology, Policlinico Tor Vergata, Rome, Italy

George E. Georges, MD
Associate Member,
Fred Hutchinson Cancer Research Center;
Associate Professor of Medicine, University of
Washington, Seattle, WA, USA

Morie A. Gertz, MD, MACP
Roland Seidler Jr. Professor of the Art of Medicine,
Mayo Medical School; Chair, Department of Medicine,
Mayo Distinguished Clinician, Mayo Clinic,
Rochester, MN, USA

Sergio A. Giralt, MD
Professor of Medicine,
Chief Attending Physician, Weill Cornell Medical
College; Chief Attending, Adult Bone Marrow
Transplant Service, Memorial Sloan-Kettering Cancer
Center, New York, NY, USA

Ted A. Gooley, PhD
Full Member,
Clinical Research Division,
Fred Hutchinson Cancer Research Center,
Duarte, CA, USA;
Affiliate Full Professor, Department of Biostatistics,
University of Washington, Seattle, WA, USA

Ajay K. Gopal, MD
Professor,
Medical Oncology Division,
University of Washington School of Medicine;
Fred Hutchinson Cancer Research Center,
University of Washington; Seattle Cancer Care Alliance,
Seattle, WA, USA

Masanori Hayashi, MD
Clinical Fellow in Pediatric Hematology–Oncology,
The Sidney Kimmel Comprehensive Cancer Center at
Johns Hopkins, Johns Hopkins University School of
Medicine, Baltimore, MD, USA

Helen E. Heslop, MD, FRACP, FRCPA
Dan L. Duncan Chair,
Professor of Medicine and Pediatrics, Center for Cell
and Gene Therapy, Baylor College of Medicine,
Houston Methodist Hospital and Texas Children's
Hospital, Houston, TX, USA

Diane Heye, BSN, OCN
Professional Practice Coordinator, Seattle Cancer Care
Alliance, Fred Hutchinson Cancer Research Center,
Seattle, WA, USA

Sangeeta Hingorani, MD, MPH
Assistant Professor,
Pediatrics, University of Washington,
Seattle Children's Hospital, Division of Nephrology,
Seattle, WA, USA

Hans H. Hirsch, MD
Professor,
Transplantation and Clinical Virology
and Division of Infection Diagnostics,
Department of Biomedicine, University of Basel;
Clinic for Infectious Diseases and Hospital
Epidemiology, University Hospital Basel,
Basel, Switzerland

Dora Y. Ho, MD, PhD
Clinical Associate Professor,
Department of Medicine,
Division of Infectious Diseases and
Geographic Medicine, Stanford University
School of Medicine School of Medicine,
Stanford, CA, USA

David M. Hockenbery, MD
Member,
Clinical Research Division,
Fred Hutchinson Cancer Research Center;
Professor of Medicine, University of Washington
School of Medicine, Seattle, WA, USA

Mary M. Horowitz, MD, MS
Chief, Division of Hematology and Oncology
Scientific Director, Center for International Blood
and Marrow Transplant Research
Medical College of Wisconsin,
Froedtert Clinical Cancer Center,
Milwaukee, WI, USA

Edwin M. Horwitz, MD, PhD
Director of Pediatric Blood and Marrow
Transplantation,
Professor of Pediatrics and Medicine,
Nationwide Children's Hospital,
The Ohio State University College of Medicine,
Columbus, OH, USA

James I. Ito, MD
Professor and Chief,
Division of Infectious Disease, City of Hope National
Medical Center, Duarte, CA, USA

Roy B. Jones, MD, PhD
Professor of Medicine,
Department of Stem Cell Transplantation and Cellular
Therapy, The University of Texas M.D. Anderson
Cancer Center, Houston, TX, USA

Carl H. June, MD
Richard W. Vague Professor in Immunotherapy,
Department of Pathology and Laboratory Medicine and
Smilow Center for Translational Research, Perelman
School of Medicine, University of Pennsylvania,
Philadelphia, PA, USA

Michael Kalos, PhD
CSO,
Cancer Immunobiology, Lilly Research Laboratories,
Eli Lilly and Company, New York, NY, USA

Jennifer A. Kanakry, MD
Head, Neoplasms of Immunodeficiency Unit,
Experimental Transplantation and Immunology
Branch, National Cancer Institute, National Institutes of
Health, Bethesda, MD, USA

Fouad R. Kandeel, MD, PhD
Professor,
Department of Diabetes and Metabolic Diseases
Research; Director, Division of Development and
Translational Diabetes and Endocrine Research;
Chair and Professor, Department of Clinical Diabetes,
Endocrinology, and Metabolism, City of Hope Medical
Center, Duarte, CA, USA

Hans-Peter Kiem, MD
Professor of Medicine,
University of Washington School of Medicine;
Member, Fred Hutchinson Cancer Research Center
Seattle, WA, USA

Amrita Krishnan, MD, FACP
Director,
Multiple Myelonia Program;
Associate Director, Medical Education and Training,
Department of Hematology/HCT, City of Hope
Medical Center, Duarte, CA, USA

Heather J. Landau, MD
Assistant Member and Assistant Attending Physician,
Adult Bone Marrow Transplant and Multiple
Myeloma Services,
Division of Hematologic Oncology, Department of
Medicine, Memorial Sloan Kettering Cancer Center;
Assistant Professor of Medicine,
Weill Cornell Medical College,
New York, NY, USA

Ginna G. Laport, MD
Professor of Medicine,
Stanford University Medical Center,
Division of Blood and Marrow Transplantation,
Stanford, CA, USA

Helen L. Leather, BPharm
Research Assistant;
Professor, Division of Hematology/Oncology,
University of Florida College of Medicine,
Gainesville, FL, USA

Stephanie J. Lee, MD, MPH
Member, Fred Hutchinson Cancer Research Center
Professor, University of Washington,
Seattle, WA, USA

Per Ljungman, MD, PhD
Professor of Hematology,
Department of Hematology, Karolinska University
Hospital; Section of Hematology, Department of
Medicine Huddinge, Karolinska Institute,
Stockholm, Sweden

Franco Locatelli, MD
Professor of Pediatrics,
University of Pavia, Pavia; Department of Pediatric
Hematology and Oncology, IRCCS, Ospedale
Pediatrico Bambino Gesù, Rome, Italy

Preface to the First Edition

The widespread application of bone marrow transplantation (BMT) to the treatment of a steadily increasing number of life-threatening hematological, oncological, hereditary, and immunological disorders is the culmination of more than four decades of research by many investigators. Early attempts in the 1950s to transplant living cells from one individual to another were carried out in the face of considerable skepticism. It was generally accepted as axiomatic that the immunological barrier to "foreign tissue" could never be overcome.

The horrors of Nagasaki and Hiroshima spurred interest in studies of the lethal effects of irradiation. It was discovered that mice given total body irradiation in doses lethal to the marrow could be protected from death by shielding the spleen or by an infusion of marrow, and that the marrow of such animals contained living cells of donor origin. These observations suggested that patients with leukemia might be given a lethal exposure of total body irradiation, which would destroy the malignant cells along with remaining normal marrow. The exposure would also destroy the immune system, making it possible to protect against lethality by a transplant of normal marrow cells.

The theory was correct, but results were disappointing. Because the procedure was both unproved and dangerous, only those patients who had no other options were considered. Except for a few patients with an identical twin donor, there were no survivors beyond a few months. Understanding of the human leukocyte antigen (HLA) system was not yet available, and little was known about the complication we now call graft-versus-host disease (GVHD). Thus, after a brief period of enthusiasm, most investigators abandoned this seemingly hopeless pursuit. Fortunately, work in animal models continued. Studies in inbred rodents defined the genetics of the major histocompatibility system and the fundamental rules of transplantation biology. Immunosuppressive drugs were developed to limit the severity of the immune reactions between donor and host. Demonstration of successful marrow transplants in the canine model using littermates matched for the major histocompatibility complex set the stage for successful transplantation of marrow between human siblings. Thus, it is clear that a long series of experimental studies in animals ultimately made human marrow transplantation possible.

By the late 1960s, much was known about the HLA system, more effective antibiotics were available, and platelet transfusions were becoming routine. Thus began the modern era of human BMT. The past 25 years have witnessed an almost exponential growth in the number of transplants being performed and the number of diseases being considered for BMT. Initially, most grafts employed marrow from an HLA-identical sibling. Autologous marrow, long known to be effective in animal systems, is now being used with increasing frequency following intensive cancer chemotherapy. Hematopoietic progenitor cells from the peripheral blood are now being used for BMT, either alone or to supplement marrow. As a result of increasing national and international cooperation, large panels of volunteer marrow donors of known HLA type are becoming available to patients whose own marrow cannot be used or who do not have a family donor.

Currently, thousands of transplants are being performed each year world-wide. With the demonstration that marrow could be transplanted and that the cure rate would be substantial, the logical step was taken to treat patients early during the course of their respective disease (i.e. in leukemia when the burden of malignant cells was relatively low and when the patient was in excellent clinical condition). With improved patient selection, development of improved tissue typing methods, availability of potent antimicrobial agents, advances in supportive care, and improved prevention of GVHD, the results of BMT have continued to improve.

Marrow transplantation is now being applied to a long list of diseases with a wide range of results depending on the disease, the type of transplant, and the stage of the disease. For some of the diseases, BMT has already proven to be the most effective therapy (e.g., some leukemias and severe aplastic anemia), whereas for others it is the only available curative treatment (e.g., thalassemia). In very rare genetic disorders, one successful BMT may establish the success of the treatment. For other more common disorders, controlled trials are necessary to define the proper role of allogeneic or autologous BMT, or therapy not involving BMT.

Only through rigorous study and long-term follow-up can novel approaches be confirmed as effective (or ineffective). For those working in the field of marrow transplantation, a source of intellectual satisfaction has been the interdisciplinary nature of the studies. A view of the wide-ranging disciplines involved can be gleaned by reading the chapter titles for this book. A successful BMT program is always a team effort. There must be cooperation between blood banks, referring physicians, radiation oncologists, immunologists, and physicians from many subspecialties. A dedicated support staff of technicians, data managers, and, above all, nurses, is crucial. The nursing team in particular is responsible for the day-to-day care of patients. Nurses not only provide the bedside management of complex protocol studies, but also bear the burden of emotional support through the difficult hospital period. They are the most readily available source of information for the patients and families day and night. Without a strong nursing team, the entire BMT program is jeopardized.

Most important are the patients who come to the transplant center with the courage to accept days, weeks, and sometimes months of discomfort in the hope of surviving a fatal disease. We must ensure that we acknowledge and respect the dignity and individuality of each patient, that we provide adequate information for informed decision making and then include patients and families in the decision process. The greatest reward for clinical investigators is to see patients reintegrated into their personal, social, and professional lives, free of their disease and its complications.

Stephen J. Forman
Karl G. Blume
E. Donnall Thomas
Summer, 1993

Preface to the Fifth Edition

Twenty-one years ago after the first edition and six years following the fourth edition of this textbook, the editors and publisher, Wiley-Blackwell, are proud to present the fifth edition of *Thomas' Hematopoietic Cell Transplantation*. The inspiration for the development of this fifth edition came from the rapid expansion of knowledge underlying transplantation biology, increased understanding of the complications of treatment, and new information related to the pathogenesis and treatment of diseases for which transplantation is utilized. The book also covers the expansion of stem-cell donor options and the genetic manipulation of cells of the hematopoietic and immune system.

In comparing this edition with the previous one, readers will find that there are new chapters focused on contributions to the field provided from basic science experiments in stem-cell biology, immunology, and tolerance. Along with these new chapters, previous contributions have been revised to reflect the deepening of our understanding of the benefits and challenges of transplantation and the impact of new therapies in the treatment of diseases for which transplant is a potentially curative therapy. In order to expand the information in each chapter, we have limited references to include only those that are most relevant.

New to the fifth edition is a companion digital edition replacing the CD ROM. The digital edition contains the entire text of the book in a searchable form and includes all the figures in a convenient downloadable format. The availability of the digital edition reflects changes in the way readers, including basic science and clinical investigators, clinicians, and nurses, access new information for both their research work and clinical care of patients.

We, the editors, also greatly appreciate the assistance of the staff at Wiley-Blackwell, who have been extremely helpful in the process of creating this new edition, now in two volumes, with a very different and modern cover presentation. The editors feel very proud to have assembled such a talented group of authors representing our colleagues who are experts in the clinical and basic science of transplantation. In addition, this edition would not have been possible without the dedicated work of our assistants, Sara E. Clark-Fuentes, Tanya Chiatovich, and, most importantly, Kimberlie Laramie. Finally, this edition honors the memory of Dr. Karl G. Blume and Dr. E. Donnall Thomas, who passed away in 2012. Their laboratory and clinical contributions helped begin and expand the field of transplantation as a curative therapy for patients suffering from leukemia and, over time, many other disorders. Both Dr. Thomas and Dr. Blume were the first two editors of the book and this edition is dedicated to them, and also to our patients and their families whose trusting partnership makes it possible to make progress and extend hope. We also honor the memory of Dr. Thomas' wife, Dottie, who we warmly consider to be the "mother" of hematopoietic cell transplantation, for her own contributions in helping Dr. Thomas and the field and for her support and editing of the first four editions of the book. They were our colleagues, mentors, and friends, and their impact will be felt in the field for many years to come.

Frederick R. Appelbaum, MD

Tribute

Our textbook honors Dr. E. Donnall Thomas, the single individual most responsible for creating the subject of this book, and Karl G. Blume, the Founder of the Transplant Programs both at City of Hope and Stanford University. Don and Karl were the first editors of this textbook and both passed away in the years following the publication of the fourth edition. We include this tribute as a remembrance of each of them, given the work that they did in their rich, professional lives to develop stem cell transplantation as a curative therapy for so many patients around the world.

E. DONNALL THOMAS, M.D.
March 15, 1920–October 20, 2012

Don was born on March 15, 1920, and was the son of a solo general practitioner in a small Texas village. As a child he often recalled accompanying his father to his small office and to patients' homes and between he and his father, they spanned the period from horse and buggy house calls to our modern high-tech medicine. Don received his B.A. and M.D. from the University of Texas where he met his wife, Dottie (September 18, 1922–January 9, 2015). Besides raising three children and eight grandchildren together, Dottie was Don's partner in every aspect of his professional life, from working in the laboratory to editing manuscripts and administering grants. Anyone who has been fortunate enough to work with Don knows that if he was the father of marrow transplantation, then Dottie was, without question, the mother, and we honor her memory as our friend and colleague in this tribute, too.

Don graduated from Harvard Medical School in 1947 and completed his internship and residency at Peter Bent Brigham Hospital in Boston. It was while in medical school that Don first became interested in normal and malignant hematopoiesis. During those years, Sidney Farber was initiating his first studies of the use of antifolates to treat children with acute leukemia, and Don witnessed the very first patient to achieve a remission with this approach. He was exposed to the pioneering work of Allan Erslev and his search for erythropoietin, and most importantly, he learned from Leon Jacobson and his studies showing that shielding the spleen protected mice from the otherwise lethal effects of total body irradiation. As data emerged that a similar irradiation protection effect could be achieved by transferring bone marrow from a nonirradiated to an irradiated mouse, Don became convinced of the clinical potential of marrow transplantation.

In 1955, Don moved to Cooperstown, New York, and the Mary Imogene Bassett Hospital, a Columbia University affiliate, where he began working on marrow transplantation both in the canine model and in humans with Dr. Joseph Ferrebee. In 1957, he published the first report on human patients, showing that complete remissions of leukemia could be achieved using total body irradiation followed by infusion of marrow from an identical twin. At that time, there was little understanding of the principles of human histocompatibility and so attempts to expand these studies to patients without identical twins were uniformly unsuccessful. These failures were the stimulus for a long series of experiments conducted by Don in the canine model, showing that it was possible to expose dogs to supralethal doses of irradiation and rescue them by reinfusing their own marrow, that the marrow could be cryopreserved, and that large doses of peripheral blood could substitute for marrow. However attempts at allogeneic transplantation in this outbred species continued to fail because of graft-versus-host disease or graft rejection.

In 1963, Don moved to Seattle and the University of Washington to become the first head of the Division of Oncology. There he developed techniques for rudimentary histocompatibility typing in the dog and, by the mid-1960s, showed that by selecting matched donors and using methotrexate posttransplant, it was possible to successfully transplant marrow between matched littermates in almost every case. At the same time, based on the work of Dausset, Payne, Amos, and others, understanding of human histocompatibility dramatically increased and so, in the late 1960s, Don made the decision to return to the subject of allogeneic transplantation in humans. He began to assemble a team of physicians, nurses, and support personnel (many of whom are still part of the current Seattle Transplant Program) and obtained a program project grant from the National Cancer Institute. In November 1968, Dr. Robert Good and his colleagues carried out the first marrow transplant from a matched sibling for an infant with immunodeficiency, and in March 1969, Don performed the first matched sibling donor transplant for a patient with leukemia.

The Seattle Transplant Program was originally housed at the Seattle Public Health Hospital, but in 1972, when the hospital was faced with closure by the federal government, the Program moved to Providence Hospital. In 1975, Don and his team moved to the newly created Fred Hutchinson Cancer Research Center, a move that provided Don with increased space, resources, and scientific collaborations. That same year, he and his colleagues published their classic *New England Journal of Medicine* paper summarizing the field of allogeneic transplantation and particularly the early Seattle experience. These results demonstrated not only the feasibility of the procedure but also that there was a plateau on the survival curves following transplantation, suggesting that some of these patients were cured with this novel technique. Don continued to lead the Clinical Research Division of the Center and its transplant program until his partial retirement in 1989. He continued writing manuscripts, delivering lectures, and participating in research discussions at the Center.

Appropriately, Don received almost every possible award for his work, including the American Society of Hematology's Henry M. Stratton Award, the General Motor's Kettering Prize, the American Society of Oncology's Karnofsky Award, the Presidential Medal of Science, and, of course, the 1990 Nobel Prize in Medicine which he shared with Joseph Murray. With each award, Don always emphasized how much of his work was a team effort. He invariably mentioned the contributions of Rainer Storb, Dean Buckner, Reg Clift, Paul Neiman, Alex Fefer, and Bob Epstein, who helped form the original Seattle Transplant Team, and of Ted Graham, who moved with Don from Cooperstown to help in the animal research. Don never failed to credit the nursing and support staff who played such a critical role in these efforts and, like Karl, always acknowledged the patients and their families who were true partners in his work.

KARL G. BLUME, M.D.
April 10, 1937–January 9, 2013

Karl G. Blume was born in Germany on April 10, 1937; he received his medical education under the mentorship of Professor Georg W. Löhr at the University of Freiburg and graduated in 1963. After graduation he undertook his residency at Marburg and then held two fellowships: one at Freiburg and the other at City of Hope in 1970 and 1971, respectively. His early work was in red cell biochemistry, and he pursued his postdoctoral fellowship under Dr. Ernest Beutler.

In 1975, after discussions with Dr. E. Donnall Thomas in Seattle and with his encouragement, Dr. Beutler decided to develop an allogeneic bone marrow transplantation (BMT) program at City of Hope and recruited Karl to return to City of Hope to establish the program. The program at City of Hope was, in many ways, derived from work and discussions that Karl had with colleagues at the Fred Hutchinson Cancer Research Center and resulted in lifelong friends from those early days of the development of transplantation to treat diseases of bone marrow and immune system origin. The first transplantation at City of Hope was performed on May 18, 1976.

Karl's clinical and research work focused on the problems that confront patients undergoing transplantation, namely, prevention of relapse, understanding the process of immune reconstitution, the treatment and prevention of graft-versus-host disease and cytomegalovirus infection management, and, among his early insights, issues related to patients' quality of life after transplantation and their long-term health. In 1981, Karl was the principal investigator for City of Hope's National Cancer Institute's first approved program project grant in transplantation, which contained projects that focused on those problems, and he organized a talented group of young laboratory and clinical scientists to work together in understanding and solving these challenges. He published the first results from City of Hope on the transplants for acute leukemia in the *New England Journal of Medicine* in 1981, showing the impact of remission status on outcome.

Based on his success at City of Hope, in 1987 Karl was recruited by Stanley Schrier and Ron Levy to begin a new transplant program at Stanford University. Thus, he again developed from scratch his second successful transplantation program, mentoring numerous young physicians and inspiring colleagues and staff to work with him in a common quest to cure patients with hematologic malignancy and return them to their normal lives. Just as he had done at City of Hope, he developed and led another successful program project grant application. He also established the Division of Blood and Marrow Transplantation at Stanford University, taking a personal interest in the lives of each of his patients, incorporating all aspects of the care team into their treatment, including nursing, social work, dietary, and physical therapy, and confirming again a model for patient care and research in use at transplant programs around the country. During that time, he trained both Rob Negrin and Nelson Chao, who went on to direct transplantation programs at Stanford University and at Duke University, respectively. Therefore, Karl was responsible for at least three of the major BMT programs in the United States, not to mention the numerous fellows he trained and mentored at City of Hope and Stanford University.

In 2000, Karl attained emeritus status at Stanford University and stepped down from the role of chief of the BMT division to develop the Stanford Cancer Institute. He continued to serve Stanford University as associate director of research in the Department of Medicine. In 2003, he directed his energies toward developing and achieving the coveted National Cancer Institute-designated cancer center status for the Stanford Cancer Institute, a first for the university.

Karl was also a driving force in 1994 in the founding of the American Society of Blood and Marrow Transplantation, now an international organization for physicians and researchers committed to serving patients with a variety of blood diseases. He was also a leader in the American Society of Hematology and, for many years, was in charge of the organization's Career Development Program. Early on, he recognized that our responsibilities were not only to our patients now but also to those who come to us in the future. He became the first honorary member of ASBMT and, with Richard O'Reilly, was the first coeditor of *The Biology of Blood and Marrow Transplantation*, the major journal in the field. Karl worked tirelessly to make it the central journal in the field, and when there were questions about the cost of the first issues, he made a personal financial donation to ensure the journal's successful launch.

Karl won many honors, both in the United States and Germany, but his major legacy is the impact he had on the thousands of patients he treated and the others he inspired to follow in his footsteps. All of us who knew and loved him knew that his highest priorities remained the quality of life of his patients and their families and the well-being of his transplantation team and those of his colleagues around the country and world. He held us all to high standards of excellence, but he maintained it with wonderful warmth, humor, and sensitivity over the decades and across continents. All of us who worked with him benefited from his respect and could always count on him to extend a helping hand and open ears, as he wanted nothing more than to help, to give of himself, and to be a force for good in this world.

In addition to his interest in music, sports – especially Stanford athletics – and the politics of the world and its impact on all of us, he was an exemplary family man. His children, Philipp and Caroline, could always rely on him for advice, affection, and guidance. In his last years, the lives and activities of his grandchildren, Adrian, Katie, Laura, Kevin, and David, were his focus and, of course, they adored him. Vera, his wife of 45 years, was his partner in his life and his work, as Dottie was to Don, and, at difficult times, always his source of strength and calm.

Although Don and Karl are most noted for their leadership and pioneering scientific achievements, for those of us who have been fortunate enough to work with them, they are equally admired for the way in which they achieved their success. They were always focused, hardworking, and uncompromising in their laboratories and especially in clinical research. They could both be demanding critics and held others accountable for their actions, yet at the same time, they were always generous with their ideas, loyal to their colleagues, and quick to deflect praise to their coworkers and help younger colleagues who chose this career.

For many of us in the field who had the privilege of knowing and working with both Don and Karl and for the many patients who are alive because of their work and dedication, the sentiment of a Hebrew proverb seems appropriate for each of them: "Say not in grief he is no more, but live in thankfulness that he was."

List of Abbreviations

AA	Amyloid A
AA	Aplastic anemia
AABB	American Association of Blood Banks
aaIPI	Age-adjusted International Prognostic Index
AAV	Adeno-associated virus
ABC	Activated B-cell-like
ABL	Abelson leukemia virus
aBMT	Autologous bone marrow transplantation
ABMTR	Autologous Blood and Marrow Transplant Registry – North America
ABVD	Doxorubicin, bleomycin, vinblastine, dacarbazine
ABW	Actual body weight
AC	Adriamycin (doxorubicin), cyclophosphamide
ACE	Adriamycin (doxorubicin), cyclophosphamide, etoposide
ACEI	Angiotensin-converting enzyme inhibitor
ACIF	Anticomplement immunofluorescence
ACIP	Advisory Committee on Immunization Practices
ACOR	Association of Online Cancer Resources
ACP	Advanced care planning
ACR	Albumin-to-urine creatinine ratio
ACS	Acute chest syndrome
ACTH	Adrenocorticotropic hormone
ACVBP	Adriamycin (doxorubicin), cyclophosphamide, vindesine, bleomycin, prednisone
AD	Autoimmune disease
ADA	Adenosine deaminase
ADCC	Antibody-dependent cell-mediated cytotoxicity
ADH	Antidiuretic hormone
ADL	Activities of daily living
AdV	Adenovirus
AEL	Acute erythroleukemia
AFP	α-Fetoprotein
AGM	Aorta–gonad–mesonephros (region)
aGVHD	Acute graft-versus-host disease
AH	Ancestral haplotype
aHCT	Autologous hematopoietic cell transplantation
AHNMD	Associated clonal hematologic non-mast-cell lineage disease
AHPCS	Autologous hematopoietic progenitor-cell support
aHR	Adjusted hazard ratio
AHRQ	Agency for Health Care Research and Quality
aHUS	Atypical hemolytic uremic syndrome
AIDS	Acquired immune deficiency syndrome
AIF	Apoptosis-inducing factor
AIHA	Autoimmune hemolytic anemia
AIRE	Autoimmune regulator
AITD	Autoimmune thyroid disease
AITL	Angioimmunoblastic T-cell lymphoma
AKI	Acute kidney injury
AKIN	Acute Kidney Injury Network
aKIR	Activating killer immunoglobulin-like receptor
AL	Amyloid light-chain
ALA	α-Lipoic acid
ALC	Absolute lymphocyte count
ALCL	Anaplastic large-cell lymphoma
ALDH	Aldehyde dehydrogenase
ALG	Antilymphocyte globulin
ALK	Anaplastic lymphoma kinase
ALL	Acute lymphoblastic leukemia
AlloHCT	Allogeneic hematopoietic cell transplantation
AlloSCT	Allogeneic stem-cell transplantation
ALP	Alkaline phosphatase
ALPS	Autoimmune lymphoproliferative syndrome
ALT	Alanine aminotransferase
AMA	Antimitochondrial antibody
AMKL	Acute megakaryoblastic leukemia
AML	Acute myeloid leukemia
ANC	Absolute neutrophil count
ANKL	Aggressive natural killer cell leukemia
AOTONJ	Antiosteoclastic therapy-associated osteonecrosis of the jaws
AP	Accelerated phase
AP-1	Activator protein-1
APACHE	Acute Physiology, Age, Chronic Health Evaluation
APBMT	Asia Pacific Blood and Marrow Transplantation
APC	Antigen-presenting cell
APECED	Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy
API	4′,6-Diamidino-2-phenylindole
APL	Acute promyelocytic leukemia
APMF	Acute panmyelosis with myelofibrosis
Ara-C	Cytosine arabinoside
ARB	Angiotensin receptor blocker
ARDS	Acute or adult respiratory distress syndrome
ARF	Acute renal failure
ARL	AIDS-related lymphoma
ARS	Acute radiation syndrome
ARSA	Arylsulfatase A
ART	Assisted reproductive technology
ASBMT	American Society for Blood and Marrow Transplantation
ASCT	Autologous stem-cell transplantation
ASO	Allele-specific oligonucleotide
ASO-PCR	Allele-specific oligonucleotide polymerase chain reaction
AST	Aspartate aminotransferase
AT	Alkyltransferase
ATG	Antithymocyte globulin
ATL	Adult T-cell leukemia
ATLL	Adult T-cell leukemia/lymphoma
ATM	Ataxia Telangiectasia Mutated
ATRA	All-*trans*-retinoic acid
AUC	Area under the curve
AutoHCT	Autologous hematopoietic cell transplantation
AVP	Arginine vasopressin
AYA	Adolescent and young adult
AZT	Zidovudine
BAEP	Brainstem auditory evoked potentials
BAFF	B-cell-activating factor
BAIAP3	Brain-specific angiogenesis inhibitor 1-associated protein 3
BAL	Bronchoalveolar lavage
BC	Blast crisis

BCC	Basal cell carcinoma
BCMA	B-cell maturation antigen
BCNA	Bicyclic nucleoside analog
BCNU	1,3-Bis(2-chloroethyl)-1-nitrosourea (carmustine)
BCR	B-cell receptor
BCR	Breakpoint cluster region
BD	Bortezomib, dexamethasone
BDP	Beclomethasone 17,21-dipropionate
BEAC	BCNU, etoposide, Ara-C (cytosine arabinoside), cyclophosphamide
BEAM	BCNU, etoposide, Ara-C (cytosine arabinoside), melphalan
BED	Biologically effective dose
BEP	Bleomycin, etoposide, cisplatin
BER	Base excision repair
BFI	Brief Fatigue Inventory
BFM	Berlin–Frankfurt–Münster
BFU-E	Burst-forming units – erythroid
BIW	Twice weekly
BL	Burkitt lymphoma
BLA	Biologics license application
BL-CFC	Blast colony-forming cell
BLS	Bare lymphocyte syndrome
BLyS	B-lymphocyte stimulator
BM	Bone marrow
BMC	Bone marrow cell
BMD	Bone mineral density
BMDW	Bone Marrow Donors Worldwide
BMFS	Bone marrow failure syndromes
BMI	Body mass index
BMSC	Bone marrow stem cell
BMSCT	Blood and Marrow Stem Cell Transplant
BMT CTN	Blood and Marrow Transplant Clinical Trials Network
BMT	Bone marrow transplantation
BMTCN	Blood and Marrow Transplantation Certified Nurse
BMTinfonet	Blood and Marrow Transplant Information Network
BMTSS	Bone Marrow Transplant Survivor Study
BNLI	British National Lymphoma Investigation
BNP	Brain natriuretic peptide
BO	Bronchiolitis obliterans
BOOP	Bronchiolitis obliterans organizing pneumonia
BPDCN	Blastic plasmacytoid dendritic cell neoplasm
BPI	Bactericidal/permeability-increasing
BPI	Brief Pain Inventory
BR	Bendamustine, rituximab
Breg	Regulatory B (cell)
BSE	Bovine spongiform encephalopathy
BSI	Brief symptom inventory
BTK	Bruton's tyrosine kinase
BTLA	B- and T-lymphocyte attenuator
BU	Busulfan
BuMel	Busulfan, melphalan
BUN	Blood urea nitrogen
C1P	Ceramide-1 phosphate
CABSI	Catheter-associated bloodstream infection
CAEBV	Chronic active Epstein–Barr virus
CALGB	Cancer and Acute Leukemia Group B
CALLA	Common acute lymphoblastic leukemia antigen
CAR	Chimeric antigen receptor
CAR	Cocksackie and adenovirus receptor
CAR	CXCL12 adventitial reticular cell
CARES	Cancer Rehabilitation Evaluation System
cART	Combination antiretroviral therapy
CB	Cord blood
CBC	Cord blood cell
CBF	Core binding factor
CBG	Corticosteroid-binding globulin
CBHC	Cord blood hemapoietic cell
CBSC	Cord blood stem cell
CBT	Cognitive–behavioral therapy
CBT	Cord blood transplantation
CBV	Cyclophosphamide, BCNU, etoposide
CC	Complete chimerism
CCG	Children's Cancer Group
CCI	Charlson Comorbidity Index
CCI	Corrected count increment
CCNU	1-(2-Chloroethyl)-3-cyclohexyl-1-nitrosourea
CCR	Cytologic complete remission
CCSG	Children's Cancer Study Group
CCyR	Complete cytogenetic remission
CDA	Cytidine deaminase
CDAD	*Clostridium difficile*-associated diarrhea
CDAI	Crohn Disease Activity Index
CDC	Centers for Disease Control and Prevention
CDC	Complement-dependent cytotoxicity
CDF	Cumulative distribution function
CDK	Cyclin/cyclin-dependent kinase
CE	Carboplatin, etoposide
CEA	Carcinoembryonic antigen
CEACAM	Carcinoembryonic-antigen-related cell-adhesion molecule
CEC	Carboplatin, etoposide, cyclophosphamide
CEL-NOS	Chronic eosinophilic leukemia-not otherwise specified
CEM	Carboplatin, etoposide, melphalan
CESD	Center for Epidemiologic Studies – Depression
CFAR	Cyclophosphamide, fludarabine, alemtuzumab, rituximab
CFH	Complement factor H
CFU	Colony-forming unit
CFU-B	Colony-forming unit – B-lymphocyte
CFU-BLAST	Colony-forming unit – blast
CFU-E	Colony-forming unit – erythroid
CFU-F	Colony-forming unit – fibrolast
CFU-GEMM	Colony-forming unit – granulocyte/erythroid/macrophage/megakaryocyte
CFU-GM	Colony-forming unit – granulocyte–macrophage
CFU-MEG	Colony-forming unit – megakaryocytic
CFU-Mix	Colony-forming unit – mixed
CFU-S	Colony-forming unit – spleen
CFU-T	Colony-forming unit – T-lymphocyte
CGD	Chronic granulomatous disease
CGH	Comparative genomic hybridization
cGVHD	Chronic graft-versus-host disease
CHD	Coronary heart disease
CHF	Congestive heart failure
CHOEP-14	Doxorubicin, vincristine, etoposide, prednisone
CHOP	Cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), prednisone
CHR	Complete hematologic response
CHRIs	Child Health Ratings Inventory
CHS	Chediak–Higashi syndrome
CI	Comorbidity index
CI	Confidence interval
CI	Cumulative incidence
CIA	Collagen-induced arthritis
CIBMTR	Center for International Blood and Marrow Transplant Research
CID	Combined immunodeficiency syndrome
CIDP	Chronic inflammatory demyelinating polyneuropathy
CIF	Cumulative incidence function
CIHHV-6	Chromosomal integration of human herpesvirus 6
CIPN	Critical illness polyneuropathy
CJD	Creutzfeldt–Jakob disease
CKD	Chronic kidney disease
CLIA	Clinical Laboratory Approved Amendments
CLL	Chronic lymphoid/lymphocytic leukemia
CLO	Clofarabine

CLP	Common lymphoid progenitor
CLR	C-type lectin receptor
CMF	Cyclophosphamide, methotrexate, fluorouracil
CMI	Cellular mediated immunity
CML	Chronic myeloid/myelogenous leukemia
CMML	Chronic myelomonocytic leukemia
CMN	Chronic myeloid neoplasm
CMP	Common myeloid progenitor
CMR	Complete molecular response
CMV	Cytomegalovirus
CMV-Ig	Cytomegalovirus antibody-enriched intravenous immunoglobulin
CMV-IP	Cytomegalovirus-associated interstitial pneumonia
CNI	Calcineurin inhibitor
CNL	Chronic neutrophilic leukemia
CNS	Central nervous system
COG	Children's Oncology Group
ConA	Concanavalin A
COP	Cryptogenic organizing pneumonia
COPE	Coping Orientations to Problems Experienced Scale
COX-2	Cyclooxygenase-2 (inhibitor)
CP	Chronic phase
CR	Complete remission
CRBSI	Catheter-related bloodstream infection
CREG	Cross-reactive group
CRM	Continual reassessment method
CRS	Cytokine release syndrome
CRVT	Catheter-related venous thrombosis
CSA	Cyclosporine A
CSF	Cerebrospinal fluid
CSF	Colony-stimulating factor
CSP	Cyclosporine
CT	Computed tomography
CT	Cyclophosphamide, thioTEPA
CTC	Cyclophosphamide, thioTEPA, carboplatin
CTC	Cytotoxic T cell
CTCL	Cutaneous T-cell lymphoma
CTD	Cyclophosphamide, thalidomide, dexamethsone
CTL	Cytotoxic T-lymphocyte
CTLA	Cytotoxic T-lymphocyte antigen
CTLP	Cytotoxic T-lymphocyte precursor
CTN	Clinical Trials Network
CTX	Cyclophosphamide
CTXD	Cancer and Treatment Distress
CTZ	Chemotactic trigger zone
CVAD	Fractionated cyclophosphamide, vincristine, adriamycin, dexamethasone
CVC	Central venous catheter
CVD	Cardiovascular disease
CVID	Common variable immune deficiency
CVRF	Cardiovascular risk factor
CVVH	Continuous veno-venous hemofiltration
CVVHDF	Continuous veno-venous hemodiafiltration
CY	Cyclophosphamide
CyBorD	Cyclophosphamide, bortezomib, dexamethasone
CYP	Cytochrome P
DAD	Direct antigen detection
DAF	Decay-accelerating factor
DAG	Diacylglycerol
DAH	Diffuse alveolar hemorrhage
DAMP	Damage-associated molecular pattern
DAS	Dasatinib
DC	Dendritic cell
DCEP	Dexamethasone, cyclophosphamide, etoposide, cisplatin
DCK	Deoxycytidine kinase
DDR	Discoidin domain receptor
DFA	Direct fluorescent antibody (test)
DFCI	Dana–Farber Cancer Institute
DFS	Disease-free survival
DGK	Deoxyguanosine kinase
DH	Double hit
DHAP	Dexamethasone, high-dose cytarabine, cisplatin
DHEA	Dehydroepiandrosterone
DHEAS	Dehydroepiandrosterone sulfate
DHFR	Dihydrofolate reductase
DHPG	9-(1,3-Dihydroxy-2-propoxymethyl)guanine (ganciclovir)
DIC	Disseminated intravascular coagulation
DILI	Drug-induced liver injury
DIPSS	Dynamic International Prognostic Scoring System
DKA	Diabetic ketoacidosis
DLA	Dog leukocyte antigen
DLBCL	Diffuse large B-cell lymphoma
DLCL	Diffuse large cell lymphoma
DLCO	Diffusion capacity of the lung for carbon monoxide
DLI	Donor lymphocyte infusion
DLT	Dose-limiting toxicity
DM	Diabetes mellitus
DMSO	Dimethyl sulfoxide
DN	Double negative
DNA	Deoxyribonucleic acid
DNAX	DNA accessory molecule
DNR	Do not resuscitate
DOTA	1,4,7,10-Tetraazacyclododecane-*N*,*N*′,*N*′′,*N*′′′-tetraacetic acid
DOTMP	1,4,7,10-Tetraazacyclododecane-1,4,7,10-tetramethylenephosphonic acid
DPC	Days post-coitum
DPTS	Delayed pulmonary toxicity syndrome
DR	Death receptor
DRG	Dorsal root ganglion
DSA	Donor-specific antibody
DSB	Double-strand break
DSII	Disease-Specific Impairment Inventory
DSRCT	Desmoplastic small round cell tumor
dsRNA	Double-stranded RNA
DST	Donor-specific transfusion
DTH	Delayed type hypersensitivity
DTI	Diffusion-tensor MRI
DTPA	Diethylenetriaminepentaacetic acid
DVT	Deep venous thrombosis
DXA	Dual-energy X-ray absorptiometry
EAE	Experimental allergic encephalomyelitis
EAE	Experimental autoimmune encephalomyelitis
EATL	Enteropathy-associated T-cell lymphoma
EB	Embryoid body
EBMT	European Group for Blood and Marrow Transplantation
EBMTR	European Bone Marrow Transplant Registry
EBNA	Epstein–Barr (virus) nuclear antigen
EBV	Epstein–Barr virus
EBV-LDP	Epstein–Barr virus-associated lymphoproliferative disorder
EC	Endothelial cell
EC	Epirubicin, cyclophosphamide
ECAT	Extracorporal adsorption therapy
ECFC	Endothelial colony-forming cells
ECG	Electrocardiogram
ECIL	European Conference on Infections in Leukaemia
ECM	Extracellular matrix
ECP	Extracorporeal photopheresis
ED	Erectile dysfunction
EDSS	Expanded Disability Status Scale
EDTMP	Ethylenediaminetetramethylenephosphonic acid
EEG	Electroencephalogram
EFS	Event-free survival
EGBMT	European Group for Blood and Marrow Transplantation
ELISA	Enzyme-linked immunosorbent assay

ELN	European LeukemiaNet
EM	Erythema multiforme
EMLA	Eutectic Mixture of Local Anesthetic
EN	Enteral nutrition
ENKL	Extranodal NK/T-cell nasal type leukemia
ENSG	European Neuroblastoma Study Group
ENU	Ethyl-*N*-nitrosourea
EORTC	European Organization for Research and Treatment of Cancer
EPC	Endothelial progenitor cell
EPO	Erythropoietin
EPOCH	Etoposide, prednisone, vincristine (Oncovin), doxorubicin hydrochloride
ER	Endoplasmic reticulum
ER	Estrogen receptor
ERIC	European Research Initiative in chronic lymphocytic leukemia
ERT	Enzyme replacement therapy
ESBL	Extended-spectrum β-lactamase
ESC	Embryonic stem cell
ESFT	Ewing sarcoma family of tumors
ET	Essential thrombocythemia
ETP	Early thymic progenitor
ETS	Euthyroid sick syndrome
EWOG	European Working Group
EWOG-MDS	European Working Group of Myelodysplastic Syndromes in Childhood
FA	Fanconi anemia
FAB	French–American–British Classification
FACIT-SP	Functional Assessment of Chronic Illness Therapy – Spirituality and Wellbeing Scale
FACS	Fluorescence-activated cell sorter
FACT	Foundation for the Accreditation of Cellular Therapy
FACT	Functional Assessment of Chronic Illness Therapies
FACT-BMT	Functional Assessment of Cancer Therapy – BMT Module
FAMA	Fluorescent-antibody staining of membrane antigen
FasL	Fas ligand
FC	Facilitator cell
FCH	Fibrosing cholestatic hepatitis
FCR	Fludarabine, cyclophosphamide, rituximab (RTX)
FDA	Food and Drug Administration
FDG	[^{18}F]Fluorodeoxyglucose
FDR	False discovery rate
FEC	Fluorouracil, epirubicin, cyclophosphamide
FEV$_1$	Forced expiratory ventilation in 1 second
FFP	Fresh frozen plasma
FFS	Failure-free survival
FHCRC	Fred Hutchinson Cancer Research Center
FISH	Fluorescence in situ hybridization
FKBP	Tacrolimus (FK)-binding protein
FL	Follicular lymphoma
FLACC	Face, Legs, Activity, Cry, Consolability (pain assessment tool)
FLAIR	Fluid attenuated inversion recovery
FLC	Free light chain
FLIPI	Follicular Lymphoma International Prognostic Index
FLU	Fludarabine
FN	Febrile neutropenia
FNA	Fine-needle aspiration
FNH	Focal nodular hyperplasia
FoxP3	Forkhead box P3
FSH	Follicle-stimulating hormone
FSI	Fatigue Symptom Inventory
FTBI	Fractionated total body irradiation
FTBI	Full total body irradiation
FTI	Farnesyltransferase inhibitor
FTOC	Fetal thymic organ culture
5-FU	5-Fluorouracil
FVC	Forced vital capacity

GA	Glatiramer acetate
GABG	German Autologous Bone Marrow Transplant Group
GALT	Gut-associated lymphoid tissue
GAP	GTPase-activating protein
GBM	Glioblastoma multiforme
G-BM	G-PBHC and/or G-CSF primed bone marrow
gc	Genome copies
GCB	Germinal center B-cell-like
G-CSF	Granulocyte colony-stimulating factor
GCT	Germ-cell tumor
GDP	Guanosine diphosphate
GEBDIS	German Breast Cancer Dose Intensity Study
GEE	Generalized estimating equation
GEL/TAMO	Grupo Español de Linfomas/Trasplante Autólogo de Médula Ósea
GEM	Gemcitabine
GEM	Grid Enabled Measures
GEP	Gene expression profiling
GF	Graft failure
GFP	Green fluorescent protein
GFR	Glomerular filtration rate
GGT	γ-Glutamyl transferase
GH	Growth hormone
GHRH	Growth hormone-releasing hormone
GHSG	German Hodgkin Study Group
GI	Gastrointestinal (tract)
GICAT	Gruppo Italiano Collaborativo AIDS e Tumori (Italian Cooperative Group on AIDS and Tumors)
GISL	Gruppo Italiano per lo Studio dei Linfomi (Italian Lymphoma Study Group)
GITMO	Gruppo Italiano per il Trapianto di Midollo Osseo
GM	Galactomannan
GM-CSF	Granulocyte–macrophage colony-stimulating factor
GMP	Granulocyte macrophage progenitor (cell)
GMP	Guanosine monophosphate
GNB	Gram-negative bacilli
GnRH	Gonadotropin-releasing hormone
gp	Glycoprotein
G-PBHC	Granulocyte colony-stimulating factor-mobilized peripheral blood hematopoietic cell
GPI	Glycosylphosphatidylinositol
GPI-AP	Glycosylphosphatidylinositol-anchored protein
GRE	Glucocorticoid response element
GSH	Glutathione (reduced)
GST	Glutathione-*S*-transferase
GTP	Good tissue practice
GTP	Guanosine triphosphate
GVD	Gemcitabine, vinorelbine, liposomal doxorubicin
GVH	Graft-versus-host
GVHD	Graft-versus-host disease
GVHL	Graft-versus-Hodgkin disease (lymphoma)
GVL	Graft-versus-leukemia
GVLE	Graft-versus-leukemia effect
GVT	Graft-versus-tumor
GWAS	Genome-wide association study
H&E	Hematoxylin and eosin (stain)
HA	Hemagglutinins
HAART	Highly active antiretroviral therapy
HADS	Hospital Anxiety and Depression Scale
HAMA	Human antimouse antibody
HA-MRSA	Healthcare-associated MRSA
HAV	Hepatitis A virus
HBoV	Human bocavirus
HBV	Hepatitis B virus
HC	Hematopoietic cell
HC	Hemorrhagic cystitis
HC	Histocompatibility complex

4-HC	4-Hydroperoxycyclophosphamide
HCG	Human chorion gonadotropin
HCoV	Human coronavirus
HCT	Hematopoietic cell transplantation
HCT-CI	HCT-Comorbidity Index
HCV	Hepatitis C virus
HD	Hodgkin disease
HDAC	High-dose Ara-C
HDC	High-dose chemotherapy
HDIT	High-dose immunosuppressive therapy
HDT	High-dose therapy
HEPA	High-efficiency particulate air
HES	Hydroxyethyl starch
HES	Hypereosinophilic syndrome
hESC	Human embryonic stem cell
HEV	Hepatitis E virus
HFTBI	Hyperfractionated total body irradiation
HGF	Hepatocyte growth factor
HGNC	HUGO Genome Nomenclature Committee
HHS	Human and Health Services
HHV	Human herpesvirus
HI	Hemagglutination inhibition
HIB	*Haemophilus influenzae* type B
HIF	Hypoxia-inducible transcription factor
HIV	Human immunodeficiency virus
HL	Hodgkin lymphoma
HLA	Human leukocyte antigen
HLH	Hemophagocytic lymphohistiocytosis
hMPV	Human metapneumovirus
HOVON	Hemato-Oncologie voor Volwassenen Nederland
HPA	Hypothalamic–piuitary–adrenal
HPC	Hematopoietic progenitor cell
HPI	Helicase–primase inhibitor
HPV	Human papillomavirus
HR	Hazard ratio
HR	Homologous recombination
HRCT	High-resolution chest tomography
HRE	Hypoxia-inducible transcription factor response element
HRhV	Human rhinovirus
HRPBC	High-risk primary breast cancer
HRQOL	Health-related quality of life
HRSA	Health Resources and Services Administration
HRT	Hormone replacement therapy
HSC	Hematopoietic stem cell
HSC	Hepatic stellate cell
HSCT	Hematopoietic stem-cell transplantation
HSDD	Hypoactive sexual desire disorder
HSPC	Hematopoietic stem/progenitor cell
HSTCL	Hepatosplenic T-cell lymphoma
HSV	Herpes simplex virus
HSV-TK	Herpes simplex virus thymidine kinase
HT	Histologic transformation
5-HT	5-Hydroxytryptamine (serotonin)
hTERT	Human telomerase reverse transcriptase
HTLV	Human T-cell lymphotropic virus
HTS	High-throughput sequencing
HU	Hydroxyurea
HUS	Hemolytic uremic syndrome
HVEM	Herpes virus entry mediator
HVG	Host-versus-graft (reaction)
IA	Invasive aspergillosis (infection)
IBCSG	International Breast Cancer Study Group
IBDIS	International Breast Cancer Dose Intensity Study
IBMTR	International Bone Marrow Transplant Registry
IBW	Ideal body weight
ICAM	Intracellular adhesion molecule
ICE	Ifosfamide, carboplatin, etoposide
ICOS	Inducible costimulator (protein)
ICOS-L	Inducible costimulator ligand
ICSI	Intracytoplasmic sperm injection
ICU	Intensive care unit
ID	Intermediate dose
iDC	Immature dendritic cells
IDO	Indoleamine 2,3-dioxygenase
IDOX	4-Iodo-4-deoxydoxorubicin
IDSA	Infectious Diseases Society of America
IE	Immediate early (antigen expression)
IEM	Inborn errors of metabolism
IFI	Invasive fungal infection
IFN	Interferon
IFRT	Involved field radiotherapy
Ig	Immunoglobulin
IGCCCG	International Germ Cell Cancer Collaborative Group
IGEV	Ifosfamide, gemcitabine, vinorelbine, prednisone
IGF	Insulin-like growth factor
IGFBP	Insulin-like growth factor binding protein
IgG	Immunoglobulin G
IgH	Immunoglobulin heavy chain
IGRT	Image-guided radiation therapy
IHC	Immunohistochemistry
IHWG in HCT	International Histocompatibility Working Group in Hematopoietic Cell Transplantation
iKIR	Inhibitory killer immunoglobulin-like receptor
IL	Interleukin
IM	Imatinib
IMGT	International ImMunoGenetics
IMID	Immunomodulatory drug
IMPDH	Inosine monophosphate dehydrogenase
IMRT	Intensity-modulated radiation therapy
IMWG	International Myeloma Working Group
IND	Improvised nuclear device
IND	Investigational new drug
iNK-T	Invariant natural killer T (cell)
iNOS	Inducible NO synthase
INR	International normalized ratio
INRG	International Neuroblastoma Risk Group
INRGSS	International Neuroblastoma Risk Group Staging System
INSS	International Neuroblastoma Staging System
INSTI	Integrase strand transfer inhibitor
IORT	Intraoperative radiotherapy
IP	Interstitial pneumonia
IP$_3$	Inositol-1,4,5-triphosphate
IPD	Invasive pneumococcal disease
IPEX	Immunodysregulation polyendocrinopathy enteropathy X-linked (syndrome)
IPFSG	International Prognostic Factor Study Group
IPI	International Prognostic Index
iPS	Induced pluripotent stem
IPS	Idiopathic pneumonia syndrome
IPS	Interstitial pneumonia syndrome
IPSS	International Prognostic Scoring System
IPV	Inactivated polio vaccine
IRB	Institutional Review Board
IRF	Interferon regulatory factor
IRSG	Intergroup Rhabdomyosarcoma Study Group
IS	Immune synapse
IS	Immunosuppressive
IS	International Scale
ISC	Intestinal stem cell
ISO	Isohemagglutinin
IST	Immunosuppressive therapy
ISW	Immune suppression withdrawal
ITAM	Immunoreceptor tyrosine-binding activation motif
ITCC	Innovative Therapies for Children with Cancer

ITD	Internal tandem duplication
ITIM	Immunoreceptor tyrosine-binding inhibition motif
iTreg	Induced regulatory T (cell)
ITT	Intent-to-treat
IUPM	Infectious units per million
IV	Intravenous
IVF	In vitro fertilization
IVF	Intravenous fluid
IVIg	Intravenous immunoglobulin
IκB	Inhibitor I kappa B
JACIE	Joint Accreditation Committee of ISCT-Europe and EBMT
JAK	Janus kinase
JALSG	Japan Adult Leukemia Study Group
JCBBN	Japan Cord Blood Bank Network
JCV	JC virus
JIA	Juvenile idiopathic arthritis
JMDP	Japan Marrow Donor Program
JMML	Juvenile myelomonocytic leukemia
K15	Cytokeratin 15
KD	Kinase domain
KGF	Keratinocyte growth factor
KIR	Killer immunoglobulin-like receptor
KM	Kaplan–Meier
KPC	*Klebsiella pneumoniae* carbapenemase
KPS	Karnofsky Performance Score
KREC	Kappa-deleting recombination excision circle
LAIV	Live attenuated influenza vaccine
LAMP	Loop-mediated isothermal amplification
LAVV	Live attenuated varicella vaccine
LBL	Lymphoblastic lymphoma
LC	Langerhans cell
LCH	Langerhans cell histiocytosis
LCL	Lymphoblastic cell lines
LD	Linkage disequilibrium
LDH	Lactate dehydrogenase
LEDGF	Lens epithelium-derived growth factor
LenDex	Lenalidomide, dexamethasone
LET	Linear energy transfer
LFA	Leukocyte function-associated antigen
LFR	Limited field radiation
LFS	Leukemia-free survival
LFS	Lung function score
LGL	Large granular lymphocyte
LH	Luteinizing hormone
LHRH	Luteinizing hormone-releasing hormone
LIF	Leukemia inhibitory factor
LMD	Laser microdissection
LMP	Latency membrane protein
LMWH	Low molecular weight heparin
LN	Lymph node
LOH	Loss of heterozygosity
LPHD	Lymphocyte-predominant Hodgkin disease
LPS	Lipopolysaccharide
LQ	Linear quadratic
LRD	Lower respiratory tract disease
LRP	Lipoprotein receptor-related protein
LRP	Lung resistance protein
LRR	Leucine-rich-repeat
LSD	Lyosomal storage disorders
LTC-IC	Long-term culture initiating cell
LTFU	Long-term follow-up
LT-HSC	Long-term hematopoietic stem cell
LUTS	Lower urinary tract syndrome
LV	Lenti virus
LVEF	Left ventricular ejection fraction
M protein	Monoclonal protein
MA	Myeloablative
mAb	Monoclonal antibody
MAC	Membrane attack complex
MAC	Myeloablative conditioning
MAFIA	Macrophage Fas-induced apoptosis
MALDI-TOFMS	Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry
MAP	High-dose methotrexate, cisplatin, and doxorubicin
MAPK	Mitogen-activated protein kinase
MBC	Metastatic breast cancer
MBL	Monoclonal B-cell lymphocytosis
MBP	Myelin basic protein
MCD	Minimal change disease
MCL	Mantle cell lymphoma
MCL	Mast cell leukemia
mCMV	Murine cytomegalovirus
M-CSF	Macrophage colony-stimulating factor
MCyR	Major cytogenetic response
MDASI	M.D. Anderson Symptom Inventory
mDC	Mature dendritic cells
MDex	Melphalan, dexamethasone
MDRD	Modification of Diet in Renal Disease (Study)
MDS	Myelodysplastic syndrome
MDSC	Myeloid-derived suppressor cell
MEAC	Minimum effective analgesic concentration
MEL	Melphalan
MEP	Megakaryocyte erythrocyte progenitor
mESC	Mouse embryonic stem cell
mesna	Sodium 2-mercaptoethanesulfonate
MetaEICESS	Meta European Intergroup Cooperative Ewing Sarcoma Study
MF	Mycosis fungoides
MF	Myelofibrosis
MFC	"Multiparametric" flow cytometric
MFC	Multidimensional flow cytometry
MFD	Matched family donor
MG	Myasthenia gravis
MGDF	Megakaryocyte growth and development factor
MGH	Massachusetts General Hospital
MGMT	Methylguanine methyltransferase
MGUS	Monoclonal gammopathy of undetermined significance
mHA	Minor histocompatibility antigen
mHAQ	Modified Health Assessment Questionnaire
MHC	Major histocompatibility complex
MHV	Mouse hepatitis virus
MIC	Minimum inhibitory concentration
MICA	MHC class I chain-related gene A
MIP-1	Macrophage inflammatory protein 1
MIPI	Mantle Cell Prognostic Index
MIRD	Medical internal radiation dose
MIRL	Membrane inhibitor of reactive lysis
miRNA	micro-RNA
mITT	Modified intent-to-treat
MJM	Muscle and Joint Measure
MKP	Megakaryocyte progenitor
MLC	Mixed leukocyte culture
MLD	Metachromatic leukodystrophy
MLL	Mixed leukemia lymphoma gene
MLL	Mixed lineage leukemia
MLR	Mixed leukocyte reaction
MLS	Maroteaux–Lamy syndrome
MM	Multiple myeloma
MMF	Mycophenolate mofetil
MMR	Major molecular response
MMR	Measles/mumps/rubella
MMRD	Mismatched related donor
MMUD	Mismatched unrelated donor

MNC	Mononuclear cell
MODS	Multiple-organ dysfunction syndrome
MOG	Myelin oligodendrocyte glycoprotein
MOPP	Mechlorethamine, vincristine (Oncovin), procarbazine, prednisone
MP	Melphalan, prednisone
MP	Methylprednisolone
MPA	Mycophenolic acid
MPAG	7-*O*-Mycophenolic acid glucuronide
MPAL	Mixed phenotype acute leukemia
MPB	Mobilized peripheral blood (cells)
MPFC	Multiparameter flow cytometry
MPN	Myeloproliferative neoplasm
MPP	Multipotent progenitor
MPT	Melphalan, prednisone, thalidomide
MPV	melphalan, prednisone, bortezomib (Velcade)
MRC	Medical Research Council
MRD	Minimal residual disease
MRI	Magnetic resonance imaging
m-RNA	Messenger RNA
MRP	Multidrug resistance-associated protein
MRS	Magnetic resonance spectroscopy
MRSA	Methicillin-resistant *Staphylococcus aureus*
mRSS	Modified Rodman skin score
MS	Mass spectrometry
MS	Multiple sclerosis
MSC	Mesenchymal stem cell
MSC	Mesenchymal stromal cell
MSCH	Mouse spinal cord homogenate
MSFC	Multiple sclerosis functional composite
MSI	Microsatellite instability
MSKCC	Memorial Sloan Kettering Cancer Center
MS-LCH	Multi-system Langerhans cell histiocytosis
MSSA	Methicillin-susceptible *Staphylococcus aureus*
MTD	Maximum tolerated dose
MTOR	Mammalian target of rapamycin
Mtvs	Mouse mammary tumor virus
MTX	Methotrexate
MUD	Matched unrelated donor
MV	Measles virus
MVA	Multivariate analysis
MZ	Marginal zone
NA	Nucleoside analog
NA-DP	Nucleoside analog diphosphate
NANT	New Approaches to Neuroblastoma Therapy
NAP1	North American Pulsed Field Type 1
NASH	Non-alchoholic steatohepatitis
NAT	Nucleic acid amplification test
NA-TP	Nucleoside analog triphosphate
nbmtLINK	National Bone Marrow Transplant link
NC	Nucleated cell
NCAM	Neural cell adhesion molecule
NCCN	National Comprehensive Cancer Network
NCHS	National Center for Health Statistics
NCI	National Cancer Institute
NCIC	National Cancer Institute of Canada
NCI-WG	National Cancer Institute – Working Group
nCR	Near complete response
NCR	Natural cytotoxicity receptor
NDK	Nucleotide diphosphate kinase
NE	Norepinephrine
NEMO	Nuclear factor-kappa B essential modulator
NER	Nucleotide excision repair
NF-AT	Nuclear factor of activated T cells
NFκB	Nuclear factor-kappa B
NGS	Next-generation sequencing
NHANES	National Health and Nutrition Examination Surveys
NHEJ	Non-homologous end-joining
NHL	Non-Hodgkin lymphoma
NHLBI	National Heart, Lung, and Blood Institute
NIH	National Institutes of Health
NIL	Nilotinib
NIMA	Non-inherited maternal antigen
NIPA	Non-inherited paternal antigen
NK	Natural killer (cell)
NK	Normal karyotype
NK-T	Natural killer T (cell)
NLR	Nucleotide-binding oligomerization domain leucine-rich-repeat-containing receptor
NM	Non-myeloablative
NMA	Non-myeloablative
NMDA	*N*-Methyl-D-aspartate
NMDP	National Marrow Donor Program
NMHCT	Non-myeloablative hematopoietic cell transplantation
NNRTI	Non-nucleoside reverse transcriptase inhibitor
NO	Nitric oxide
NOD	Non-obese diabetic (mouse)
NOD	Nucleotide-binding oligomerization domain
NPC	Nasopharyngeal carcinoma
NRM	Non-relapse mortality
NRS	Neurological Rating Scale
NRTI	Nucleoside reverse transcriptase inhibitor
NS	Nephrotic syndrome
NS	Noonan syndrome
NSAID	Non-steroidal anti-inflammatory drug
N-SH2	N-Terminal src-homology 2
NST	Non-myeloablative stem-cell transplantation
NT-proBNP	N-Terminal fragment of pro-brain natriuretic peptide
nTreg	Naturally occurring regulatory T (cell)
NWTS	National Wilms Tumor Study
NZB	New Zealand black
NZW	New Zealand white
OATP	Organic anion-transporting polypeptide
OCTP	Organic cation-transporting polypeptide
OFAR	Oxaliplatin, fludarabine, cytarabine, rituximab
OLD	Obstructive lung disease
ONJ	Osteonecrosis of the jaw
ONS	Oncology Nursing Society
OPA	Office of Patient Advocacy
OPG	Osteoprotegerin
OPM	Oropharyngeal mucositis
O-PRISM	Oncologic Pediatric Risk of Mortality
OR	Odds ratio
OS	Overall survival
PACT	Psychological Assessment of Candidates for Transplantation Scale
PAD	Bortezomib, adriamycin, dexamethasone
PALE	Post-transplant acute limbic encephalitis
PAM	Pretransplant assessment of mortality
PAMP	Pathogen-associated molecular pattern
PAS	Periodic acid–Schiff
PB	Peripheral blood
PBHC	Peripheral blood hematopoietic cell
PBHCT	Peripheral blood hematopoietic cell transplantation
PBL	Peripheral blood lymphocyte
PBMC	Peripheral blood mononuclear cell
PBMTC	Pediatric Blood and Marrow Transplant Consortium
PBPC	Peripheral blood progenitor cell
PBSC	Peripheral blood stem cell
PCA	Patient-controlled analgesia
PCNSL	Primary central nervous system lymphoma
PCORI	Patient-Centered Outcomes Research Institute
PCR	Polymerase chain reaction
PCR	Programmed cell renewal

PCT	Pulmonary cytolytic thrombi
PCV	Pneumococcal conjugate vaccine
PCV	Protein conjugate vaccine
PD	Programmed death
PD	Progressive disease
PDC	Plasmacytoid dendritic cell
PDE	Phosphodiesterase
PDGFA	Platelet-derived growth factor A chain
PDGFR	Platelet-derived growth factor receptor
pDLI	Preemptive donor lymphocyte infusion
PDQ	Physician Data Query
PedsQL	Pediatric Quality of Life Inventory
PEGS	Platinum, etoposide, gemcitabine, methylprednisolone
PERDS	Peri-engraftment respiratory distress syndrome
PET	Positron emission tomography
PETHEMA	Programa para el Tratamiento de Hemopatías Malignas
PFS	Progression-free survival
PFT	Pulmonary function test
PGD	Pre-implantation genetic diagnosis
P-gp	P-glycoprotein
Ph	Philadelphia (chromosome)
PH	Pulmonary hypertension
PHA	Phytohemagglutinin A
PHN	Post-herpetic neuralgia
PHQ-9	Patient Health Questionnaire-9
PI	Protease inhibitor
PI3K	Phosphatidylinositol 3-kinase
PICC	Peripherally inserted central venous catheter
PID	Primary immunodeficiency disease
PIG-A	Phosphatidylinositol glycan-A
PIP$_2$	Phosphatidylinositol 4,5-diphosphate
PIP$_3$	Phosphatidylinositol 3,4,5-triphosphate
PIQ	Performance IQ
PJP	*Pneumocystis jirovecii* pneumonia
PK	Pharmacokinetic
PKC	Protein kinase C
PlGF	Placental growth factor
PLL	Prolymphocytic leukemia
PLP	Proteolipid protein
PLPHA	Postlumbar puncture headache
PMC	Persistent mixed chimerism
PMF	Primary myelofibrosis
PMGCT	Primary mediastinal germ-cell tumor
PML	Progressive multifocal leukoencephalopathy
PMN	Polymorphonuclear neutrophil
PN	Parenteral nutrition
PN	Peripheral neuropathy
PNET	Primitive neuroectodermal tumor
PNH	Paroxysmal nocturnal hemoglobinuria
PNH-sc	Subclinical paroxysmal nocturnal hemoglobinuria
POEMS	Polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes
POF	Premature ovarian failure
POG	Pediatric Oncology Group
POLST	Physician Orders for Life Sustaining Treatment
PomDex	Pomalidomide, dexamethasone
PORN	Progressive outer retinal necrosis
PORT	Patient Outcomes Assessment Research Team
PPI	Proton pump inhibitor
PR	Partial remission or partial response
PR	Progesterone receptor
PR3	Proteinase 3
PRCA	Pure red cell aplasia
PRES	Posterior reversible encephalopathy syndrome
PRO	Patient-reported outcome
PROMIS	Patient-Reported Outcomes Measurement Information System
PRR	Pathogen recognition receptor
PRST	Pediatric Registry for Stem Cell Transplantations
PSA	Prostate-specific antigen
PSC	Pluripotent stem cell
PSE	Prednisone
PSQI	Pittsburgh Sleep Quality Index
PT	Pertussis toxoid
PTA	Peripheral tissue antigen
PTCL	Peripheral T-cell lymphoma
PTCL-nos	Peripheral T-cell lymphoma not otherwise specified
PTH	Parathyroid hormone
PTLD	Post-transplant lymphoproliferative disorder
PTPase	Protein tyrosine phosphatase
PUVA	Psoralen–ultraviolet A irradiation (treatment)
PV	Polycythemia vera
PVR	Polio virus receptor
PyVAN	Polyomavirus-associated nephropathy
PyVHC	Polyomavirus-associated hemorrhagic cystitis
QALY	Quality-adjusted life-year
QLQ	Quality of Life Questionnaire
QOL	Quality of life
qRT-PCR	Quantitative reverse transcription polymerase chain reaction
QTL	Quantitative trait loci
QW	Once weekly
RA	Refractory anemia
RA	Retinoic acid
RA	Rheumatoid arthritis
RA	Right atrium
RAb	Radiolabeled antibody
RAEB	Refractory anemia with excess blasts
RAEB-T	Refractory anemia with excess blasts in transformation
RANKL	Receptor activator of nuclear factor **k**appa B ligand
RARS	Refractory anemia with ringed sideroblasts
RBC	Red blood cell
RCC	Ratio of costs to charges
RCC	Refractory cytopenia of childhood
RCC	Renal cell carcinoma
R-CHOP	Rituximab, cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), prednisone
RCMD	Refractory cytopenia with multilineage dysplasia
RCR	Replication competent retrovirus
RCT	Randomized controlled trial
REAL	Revised European–American Lymphoma
R-EPOCH	Rituximab, etoposide, prednisone, vincristine (Oncovin), doxorubicin hydrochloride
RES	Reticuloendothelial system
R-ESHAP	Rituximab, etoposide, cytarabine, cisplatin, methylprednisolone
RFS	Relapse-free survival
Rh	Rhesus
rHBV	Recombinant hepatitis B vaccine
RHC	Residual host cells
rhGH	Recombinant human growth hormone
r-hIL-7	Recombinant human interleukin-7
rHuEPO	Recombinant human erythropoietin
R-hyperCVAD	RTX (rituximab), vincristine, doxorubicin, dexamethasone
RI	Relapse incidence
RIC	Reduced-intensity conditioning
RICR	Reduced-intensity conditioning regimen
RIFLE	Risk, injury, failure, loss, end-stage
RISC	RNAi-induced silencing complex
RIT	Radioimmunotherapy
RLD	Restrictive lung disease
RLR	Rig-1-like receptor
RN	Registered nurse

RNAi	RNA interference
RNR	Ribonucleotide reductase
ROC	Receiver-operating characteristic
ROS	Reactive oxygen species
RR	Relapse rate
RR	Relative risk
RR	Response rate
RRE	Rev response element
RRE	Risk ratio estimate
RRMS	Relapsing–remitting multiple sclerosis
RRT	Regimen-related toxicity
RSCH	Rat spinal cord homogenate
RSCL	Rotterdam Symptom Checklist
RSV	Respiratory syncytial virus
RT	Reverse transcriptase
RTE	Recent thymic emigrant
RTID	Respiratory tract infectious disease
RT-PCR	Real-time polymerase chain reaction
RTQ	Real-time quantitative
RTX	Rituximab
RVD	Revlimid/lenalidomide, Velcade/bortezomib, dexamethasone
S1P	Sphingosine-1 phosphate
SAA	Serum amyloid A
SAA	Severe aplastic anemia
SAAG	Serum-ascites albumin gradient
SAHA	Suberoylanilide hydroxamic acid
SAP	Serum amyloid protein P
SARS	Severe acute respiratory syndrome
SAS-SR	Social Adjustment Scale – Self Report
SBT	Sequence-based typing
SCC	Squamous cell carcinoma
SCD	Sickle cell disease
SCF	Stem-cell factor
scFv	Single-chain variable fragment
SCID	Severe combined immunodeficiency syndrome
SCID-hu	Severe combined immunodeficiency syndrome/human (mouse)
SCL	Stem-cell leukemia
SCT	Stem-cell transplantation
SCTOD	Stem Cell Therapeutics Outcomes Database
SD	Stable disease
SD	Standard deviation
SDC	Standard-dose chemotherapy
SDF	Stroma cell-derived factor
SDS	Shwachman–Diamond syndrome
SE	Standard error
SEC	Sinusoidal endothelial cell
SEER	Surveillance Epidemiology and End Results
Sema	Semaphorin
SEREX	Serological identification of antigens by recombinant expression cloning
SERM	Selective estrogen response modulator
SF-36	Medical Outcomes Study Short Form 36
SFGM	Société Française de Greffe de Moelle
SFK	SRC-family kinase
SFOP	Société Française de l'Oncologie Pédiatrique, French Society of Pediatric Oncology
SFQ	Sexual Function Questionnaire
SGOT	Serum glutamic-oxaloacetic transaminase
SHBG	Sex hormone-binding globulin
SHEA	Society for Healthcare Epidemiology of America
Shh	Sonic hedgehog
SHM	Somatically hypermutated
SI	Stimulation index
SIADH	Syndrome of inappropriate antidiuretic hormone
SIG	Special Interest Group
sIgm	Cell surface immunoglobulin M
siRNA	Short interfering RNA

SJS	Stevens–Johnson syndrome
SKD	Severe keratinocyte dysplasia
SLAM	Signaling lymphocyte activation molecule
SLD	Sublethal damage
SLE	Systemic lupus erythematosus
SLEDAI	SLE Disease Activity Index
SM	Systemic mastocytosis
SMILE	Ddexamethasone, methotrexate, ifosfamide, L-asparaginase, etoposide
SMN	Subsequent malignant neoplasm
SMR	Standardized mortality ratio
SNP	Single nucleotide polymorphism
SNRI	Serotonin–norepinephrine reuptake inhibitor
SNS	Sympathetic nervous system
SOFA	Sequential (or sepsis-related) Organ Failure Score
SOP	Standard operating procedure
SOS	Sinusoidal obstruction syndrome
SOT	Solid organ transplantation
SP	Surfactant protein
SPECT	Single photon emission computed tomography
SR	Sensitive relapse
SR	Standard risk
SS	Sézary syndrome
SSA	Sex steroid ablation
SSA	Single-strand annealing
SSc	Systemic sclerosis
SSD	Source-to-skin distance
SSOP	Sequence-specific oligonucleotide probe
SSP	Sequence-specific primer
SSRI	Selective serotonin reuptake inhibitor
SST	Short Syntachten Test
STAMP-I	Cyclophosphamide, cisplatin, BCNU
STAMP-V	Cyclophosphamide, carboplatin, thioTEPA
STATs	Signal transducers and activators of transcription
STBI	Single-fraction total body irradiation
ST-HSC	Short-term hematopoietic stem cell
STING	Stimulator of interferon genes
STR	Short tandem repeat
SVC	Superior vena cava
SWOG	Southwest Oncology Group
T1DM	Type 1 diabetes mellitus
T3	Triiodothyronine
T4	Thyroxine
TAA	Tumor-associated antigen
TAAM	Time-averaged mean of the maximum
TACL	Therapeutic Advances in Childhood Leukemia
TAD	Thalidomide, adriamycin, dexamethasone
TA-GVHD	Transfusion-associated graft-versus-host disease
TAI	Thoracoabdominal irradiation
TAM	Transplant-associated microangiopathy
t-AML	Therapy-related acute myeloid leukemia
TAP	Transporter associated with antigen processing
TAR	Tat response element
TBI	Total body irradiation
TCA	Tricyclic antidepressant
TCD	T-cell depletion
TCD	Transcranial Doppler (ultrasonography)
TCE	T-cell epitope
T_{CM}	Central memory T (cells)
Tcon	Conventional T
TCR	T-cell receptor
TD	Thalidomide, dexamethasone
TDM	Therapeutic drug monitoring
TdT	Terminal deoxynucleotidyl transferase
TED	Thromboembolic disease
T_{EM}	Effector memory T (cell)
TEN	Toxic epidermal necrolysis

TEPA	*N*-Triethylenephosphoramide
TEPC	Thymic epithelial progenitor cell
TERS	Transplant Evaluation Rating Scale
TERT	Telomerase reverse transcriptase
TF	Tissue factor
T_{FH}	T follicular helper
TFIIH	Transcription factor IIH complex
TFPI	Tissue factor pathway inhibitor
TG	Triglyceride
TGF-β	Transforming growth factor beta
T-GVHD	Transfusion-associated graft-versus-host disease
TH	Helper T-lymphocytes
T_H	T helper
thioTEPA	*N*-Triethylenethiophosphoramide
TICE	Paclitaxel, ifosfamide followed by high-dose carboplatin, etoposide
TIL	Tumor-infiltrating lymphocytes
TIP	Paclitaxel, ifosfamide, cisplatin
TIV	Trivalent influenza vaccine
TK	Thymidine kinase
TKI	Tyrosine kinase inhibitor
TLC	Total lung capacity
TLI	Total lymphoid irradiation
TLR	Toll-like receptor
TLS	Tumor lysis syndrome
TM	Thalassemia major
TMA	Thrombotic microangiopathy
TMD	Temporomandibular dysfunction
t-MDS	Therapy-related myelodysplastic syndrome
TMEV	Theiler's murine encephalomyelitis virus
TMI	Total marrow irradiation
TMLI	Total marrow and lymphoid irradiation
TMP–SMX	Trimethoprim–sulfamethoxazole
TM–SLF	Trimethoprim–sulfamethoxazole
TNC	Total nucleated cell
TNF	Tumor necrosis factor
TNFR	Tumor necrosis factor receptor
TNF-α	Tumor necrosis factor α
TOI	Trial Outcome Index
TPA	Tissue plasminogen activator
T-PLL	T-cell prolymphocytic leukemia
TPN	Total parenteral nutrition
TPO	Thrombopoietin
TR	Tandem repeat
TRAIL	TNF-related apoptosis-inducing ligand
TRALI	Transfusion-related acute lung injury
TREC	T-cell receptor excision circles
Treg	Regulatory T (cell)
Treo	Treosulfan
TRM	Transplant-related mortality
TRT	Testosterone replacement therapy
TRV	Tricuspid regurgitation velocity
TSH	Thyroid-stimulating hormone
TSLP	Thymic stromal lymphoietin
TT	*N*-Triethylenethiophosphoramide, thioTEPA
TTP	Thrombotic thrombocytopenic purpura
TTR	Transthyretin

UBC	Umbilical cord
UCB	Umbilical cord blood
UCB	Unrelated cord blood
UCBT	Umbilical cord blood transplant
UGT	Uridine 5′-diphosphate glucuronosyltransferase
UPD	Uniparental disomy
URD	Unrelated donor
URI	Upper respiratory tract infection
UV	Ultraviolet
VAD	Vincristine, adriamycin, dexamethasone
VATS	Video-assisted thoracoscopic surgery
VBAD	Vincristine, BCNU, doxorubicin, dexamethasone
VBMCP	Vincristine, BCNU, melphalan, cyclophosphamide, prednisone
VCD	Velcade/bortezomib, cyclophosphamide, dexamethasone
VDCR	Velcade/bortezomib, dexamethasone, cyclophosphamide, Revlimid/lenalidomide
VDR	Vitamin D receptor
VE	Vascular endothelial
VEGF	Vascular endothelial growth factor
VeIP	Vinblastine, ifosfamide, cisplatin
VF	Ventricular fibrillation
VGPR	Very good partial remission
VIC	Virus isolation by cell culture
VIP	Etoposide, ifosfamide, cisplatin
VIP	Vasoactive intestinal peptide
VISA	Vancomycin-intermediate *Staphylococcus aureus*
VLCFA	Very long-chain fatty acid
VNTR	Variable number of tandem repeat
VOD	Veno-occlusive disease
VRE	Vancomycin-resistant *Enterococcus*
VSAA	Very severe aplastic anemia
VT	Ventricular tachycardia
VTD	Velcade/bortezomib, thalidomide, dexamethasone
vWF	von Willebrand factor
VWMD	Vanishing white matter disease
VZIG	Varicella zoster immune globulin
VZV	Varicella zoster virus
WAS	Wiskott–Aldrich syndrome
WBC	White blood cell
WBM	Whole bone marrow
WBMT	Worldwide Network for Blood & Marrow Transplantation
WBRT	Whole-brain radiotherapy
WES	Whole exome sequencing
WGA	Wheat germ agglutinin
WGS	Whole genome sequencing
WMDA	World Marrow Donor Association
WNV	West Nile virus
WPSS	WHO classification-based Prognostic Scoring System
WSG	West German Study Group
wt	Wild-type
X-ALD	X-linked adrenoleukodystrophy
XRT	External-beam radiotherapy

CHAPTER 1

A History of Allogeneic and Autologous Hematopoietic Cell Transplantation

Karl G. Blume[1] **and E. Donnall Thomas**[2]
[1] Stanford University School of Medicine, Stanford, CA, USA
[2] University of Washington School of Medicine, Seattle, WA, USA

How it all began

In the Fall of 1868, two experimental pathologists reported their important observations that blood cells of mammals are produced inside the bone marrow and that the mature cells leave the marrow cavity through small blood vessels that penetrate the bone cortex. Neumann [1] from the University at Königsberg in Prussia (this town is now known as Kaliningrad and is part of Russia) had made his observations in rabbits, and Bizzozero [2] had worked at the University of Pavia in Italy with mice and rabbits. Both reports from these two investigators appeared less than 6 weeks apart and both men deserve to be mentioned as the original contributors of this critical finding.

Soon, physicians of leukemia patients eagerly used the exciting news from Neumann and Bizzozero and began treatments that appear rather bizarre to the current reader. Prescriptions detailed that patients should swallow fresh bone marrow from young cattle mixed with equal amounts of orange juice or that they should ingest one dessert spoon full of ox bone marrow three times daily [3]. Apparently, these "therapies" were employed based on the assumption that leukemia was a deficiency disease rather than with the expectation of cellular engraftment. Successes were not reported and for the next seven decades there was little progress in the promise of therapies using bone marrow.

In 1939, an attempt was made to inject a few milliliters of ABO matched bone marrow cells into the sternum of a patient with marrow aplasia, but a response was not achieved [4]. During the same decade, the immunologic basis for tumor transplants was established through experiments in mice [5] and led to the recognition of the H2 transplantation antigen system [6].

The explosion of the two atomic bombs at the end of World War II and the consequences of radiation on the bone marrow function of survivors of the nuclear exposure stimulated the interest in marrow transplantation again. When Medawar [7] established the immunologic basis for graft rejection and demonstrated neonatal tolerance in mice, the stage was set for the development of hematopoietic cell transplantation (HCT), and enhanced the level of interest of the medical scientific community in this subject.

History of allogeneic HCT

1949–1956: The humoral versus the cellular hypotheses

In 1949, experiments by Jacobson et al. [8] demonstrated that mice could survive lethal irradiation exposure if their spleens were shielded by lead foils. The investigators attributed their observations to a humoral or hormonal factor. In 1951, Lorenz and colleagues [9] reported that a similar protective effect could be attained by the infusion of cells from the spleen or bone marrow of mice. These two observations became the subject of a scientific debate, that is, whether the marrow recovery was possibly the consequence of humoral or of cellular mechanisms, respectively. In 1954, experiments by Barnes and Loutit [10] indicated that the recovery conferred by spleen and marrow cell infusion might be due to living cells, supporting the cellular hypothesis. In the following year, Main and Prehn [11] described studies of lethally irradiated mice being protected by marrow infusion. When their transplanted animals were given skin grafts from their respective marrow donors, skin implants from the donor animal were not rejected, providing proof of acquired tolerance that could only be explained by the transfer of living donor cells. Final proof for the cellular hypothesis came in 1956 when Ford and colleagues [12] showed that the marrow of transplanted mice displayed the cytogenetic characteristics of the donor. In this article by Ford et al. [12], the term "radiation chimera" was introduced into the scientific transplant literature. A most exciting observation was contributed also in 1956, when Barnes and colleagues [13] reported on the treatment of murine leukemia with high-dose irradiation followed by marrow graft infusion.

1956–1959: Early efforts in clinical marrow transplantation

The promising pre-clinical studies described above created considerable enthusiasm on the part of clinical investigators. First attempts to treat patients with total body irradiation and chemotherapy with subsequent marrow grafting were reported in 1957 by Thomas et al. [14]. In 1959, the same group [15] described their experience with two patients with advanced leukemia who were exposed to high-dose irradiation followed by the infusion of marrow from their identical twins. Prompt hematologic recovery was observed and the two patients survived for several months; however, then both succumbed to disease recurrence. Worldwide, approximately 200 clinical transplant procedures were performed between the mid-1950s and the

early 1960s. A retrospective review (published 1970) [16] indicated that none of the transplant recipients had become long-term survivors, and the future for HCT was generally considered bleak. Reasons for treatment failure and the resulting pessimism included the lack of reliable tissue typing methods to identify suitable donors and problems related to the lack of effective supportive care measures such as potent antibiotics and transfusional support with platelets. Also, the phenomenon of graft-versus-host disease (GVHD) which had been first encountered in animal studies, was occurring in human allogeneic HCT recipients.

In 1958, a nuclear accident occurred at the Boris Kidrich Institute in Vinča, Yugoslavia (now in Serbia) during which six laboratory workers were exposed to 2.0 to 4.3 Gy. Following this highly publicized event, the patients were flown to Paris where a team of physicians under the leadership of Dr. Mathé were given human blood-forming tissues such as fetal liver cells, spleen and bone marrow cells. The patient who had been exposed to the highest amount of radiation succumbed after a massive hemorrhage while the remaining five patients eventually recovered their bone marrow function. Although some evidence of transient engraftment was presented, it is uncertain whether the administration of the allogeneic grafts had played a role in the recovery process [17].

1955–1967: Progress in animal models of allogeneic HCT

It was apparent from the initial negative clinical experience that more information in the field of transplantation biology and improvement in the area of supportive care were necessary. Two types of animals seemed especially suitable for such studies, the inbred murine and the out-bred canine models. It was shown in mice that intravenous infusion was the optimal route for administration of bone marrow grafts [18]. Billingham and Brent [19] found that allogeneic marrow cells could cause a "wasting" syndrome, later identified as GVHD. Uphoff [20] reported that genetic factors controlled the immune reactions against the host. She also detected that methotrexate could ameliorate GVHD [21].

A report by Main and Prehn [11] raised great interest in the possibility that a marrow graft followed by a solid organ graft – such as a kidney from the same donor – might facilitate durable engraftment of the solid organ. One such effort was reported in 1959 by Mannick et al. [22] who had administered high-dose irradiation and bone marrow from an unrelated dog followed by a kidney transplant from the same donor animal. The dog eventually died of pneumonia but had a cellular marrow and no signs of rejection of the kidney. It would take an additional four decades until this attractive concept would become a successful approach in human organ transplantation medicine, that is, allowing for the eventual discontinuation of immunosuppressive therapy of the transplant patients. This approach is an intriguing alternative to life-long immunosuppression – another impressive example of successful translational research (see section on reduced intensity regimens later).

Continued studies in the dog model showed the characteristic spectrum of complications, as well as favorable events following allogeneic marrow grafting, including primary graft failure and secondary graft rejection, as well as GVHD but also stable engraftment and survival without GVHD [23]. Another important observation from the early 1960s which would have a major impact on clinical transplantation practices a quarter of a century later indicated that hematopoietic cells for engraftment could not only be harvested from the bone marrow but could also be obtained from the peripheral blood in both mice [24] and dogs [25].

In Europe, Dausset [26], as well as van Rood et al. [27], described in 1958 the human leukocyte antigen (HLA) groups. It was soon recognized that these antigens represent important genetic factors for donor selection in experimental and clinical transplantation medicine.

Studies by Epstein et al. [28] of the canine leukocyte antigen system proved that dog leukocyte antigens (DLA) were crucial in determining the outcome of allogeneic marrow transplantation in the canine model. Storb et al. [29] reported that dogs given irradiation and a marrow graft from DLA mismatched litter mates died due to graft rejection or GVHD, whereas most recipients of DLA matched marrow, especially when given post-transplant methotrexate to suppress the graft-versus-host reaction, became long-term survivors [30,31].

While these important and informative pre-clinical studies were performed in mice and dogs, a few clinical transplants were done at the same time. Mathé and colleagues [32] performed an allogeneic marrow transplantation procedure in a patient with leukemia. However, the transplant recipient eventually died with serious problems that were likely complications of chronic GVHD. Continued success with transplantation between identical twins signaled the potential of marrow grafting from histocompatible donors.

The pre-clinical observations described earlier and the increasing knowledge of the HLA system to identify compatible family members as marrow donors, as well as the improvement of supportive care measures now available, encouraged clinical investigators to plan new attempts of marrow grafting in patients with suitably matched sibling donors.

1968–1975: The beginning of the modern era of human marrow transplantation

In 1968 and 1969, three infants with congenital immunodeficiency disorders received successful marrow transplants from HLA matched siblings [33–35]. All three patients engrafted, promptly restored their previously deficient immune function, and grew up to become healthy adults [36]. It is a startling coincidence that it took exactly a full century from the two observations of Neumann [1] and Bizzozero [2] in 1868, namely that the bone marrow produces all blood cells, until 1968, when the first successful and curative bone marrow transplants were performed.

Marrow transplantation from sibling donors for patients with advanced leukemia or bone marrow failure conditions proved considerably more challenging than transplantation for immunodeficiency diseases. In 1969, the transplant group in Seattle [37] conditioned a patient in blast crisis of chronic myeloid leukemia (CML) with total body irradiation followed by marrow grafting from a histocompatible sibling. The patient engrafted, however, later succumbed to cytomegalovirus (CMV)-associated pneumonia, a complication for which no drugs had yet been developed. Successful transplant efforts for aplastic anemia patients were reported in 1972 [38]. In a seminal report in 1975, the Seattle transplant team [39] described their observations of the first 100 patients, 73 treated for advanced leukemia and 37 for aplastic anemia. Successful outcomes were noted in 50% of the aplastic anemia patients, and an ever increasing number of patients with leukemia were surviving in remission (Figure 1.1).

1976–1989: Widening application of allogeneic marrow grafting for human patients

Long-term disease-free survival of patients with leukemia was first achieved and reported by the group from Seattle in 1977 [40,41]. These patients had – without exception – failed the best available chemotherapy combinations at least once and many of them were

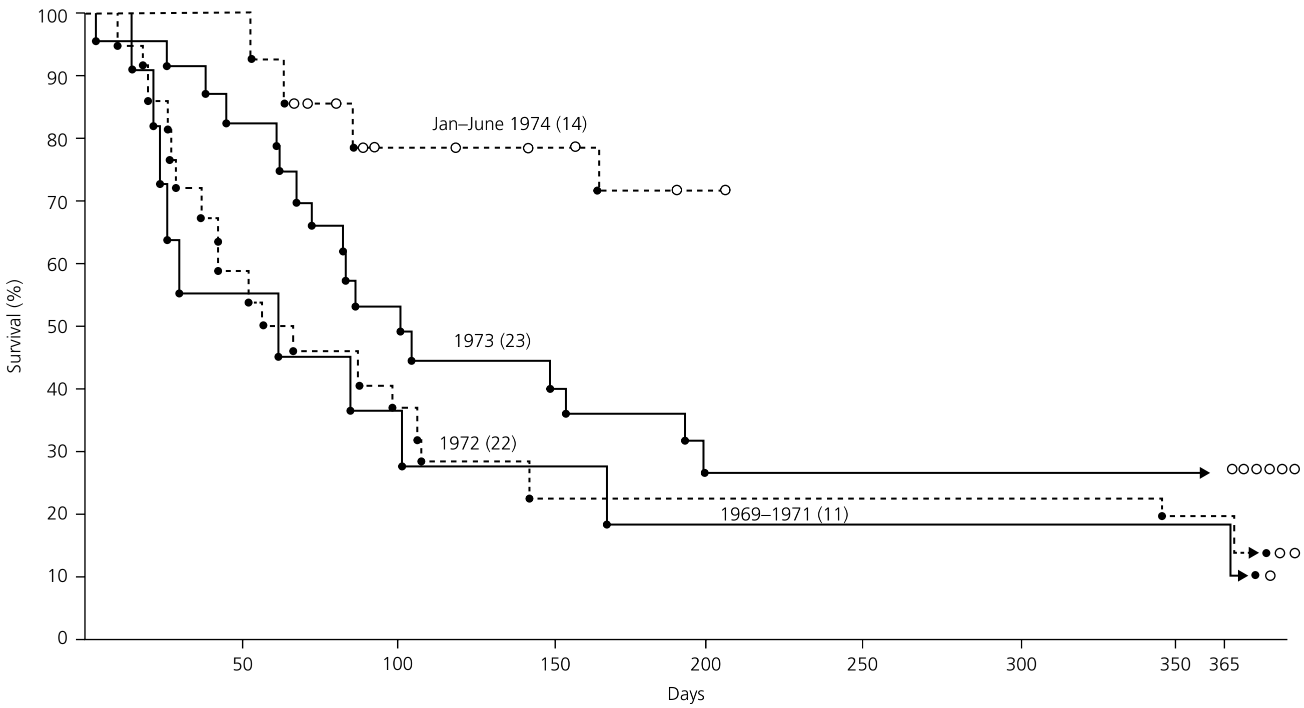

Figure 1.1 Survival curves of 70 patients with acute leukemia transplanted with a marrow graft from a histocompatible sibling in Seattle between 1969 and 1974. Source: Thomas et al. 1975 [39]. Reproduced with permission of the Massachusetts Medical Society.

treated in florid relapse. With a follow-up period of 1 to 4.5 years, 13 of 100 recipients of grafts from their sibling donors were alive and well at the time of the analysis, indicating that even some of such high-risk patients could be cured.

Considering that relapse was a major contributor to post-transplant treatment failure, it was logical to explore HCT as a curative concept in patients with acute leukemia who were in first complete remission, that is, at a time when the burden with malignant cells was relatively low and the abnormal clone was not yet resistant to high-dose radiochemotherapy. In 1979, two centers [42,43] reported their favorable experience with transplant candidates who had received their grafts from matched sibling donors while in first remission. These observations demonstrated greatly improved results compared to patients who were treated in advanced condition. It was demonstrated by further studies that the remission status at the time of HCT had a major influence on the long-term outcome of HCT [44]. The major impact of the burden of malignant cells at the time of HCT has been demonstrated over the past three decades in study after study. A recent report shows again the superior outcome in 49 patients with Philadelphia chromosome positive acute lymphoblastic leukemia transplanted in first remission compared to 30 patients who had relapsed at least once prior to HCT; see Figure 1.2. In this long-term follow-up study, patients were 2–57 years old (median age, 36 years). Age did not have an effect on the outcome of HCT [45], see Figure 1.2.

Another hematologic malignancy for which HCT was explored with curative potential was CML. Initial observations by Fefer et al. [46] indicated the disappearance of the Philadelphia chromosome in four patients after radio-chemotherapy and marrow grafting from their identical twin donors. Subsequently, HCT from matched siblings was tested in two patients with CML and established that the abnormal clone could be abrogated [47,48]. These limited but promising observations led to two larger and successful trials on HCT from matched siblings for CML patients who were still in the chronic phase of their disease [49,50].

The first transplants for thalassemia major [51] and for sickle cell disease [52] were performed during the 1980s in Seattle and opened the field for successful correction of severe non-malignant hematologic disorders.

During this time, new approaches for the prevention of GVHD were developed in animal models and were tested clinically [53,54]. The potent combination of cyclosporine with methotrexate was introduced and became a new standard, while efforts to remove T cells from the marrow inoculum were shown to be also a powerful approach to prevent GVHD [55,56].

Alternatives to the frequently employed preparatory regimen of irradiation and cyclophosphamide were explored in clinical trials, for example, a combination of busulfan with cyclophosphamide [57,58] or total body irradiation in combination with etoposide [59,60].

Another critical event with future consequences occurred in the 1980s: The National Marrow Donor Program was founded in 1987, and succeeded over the next 25 years in recruiting 20 million volunteers from all continents to serve as unrelated HCT donors. This international organization had been preceded in its efforts by the British Anthony Nolan Foundation. Following the first successful transplant procedure [61] using a graft from an unrelated volunteer, HCT from such donors has grown to a point that several cell collections from unrelated donors occur daily and are transported by couriers from donor facilities to the respective transplant centers – with approximately half of the transplants occurring on an international basis.

In 1986, another major nuclear accident occurred at the Chernobyl Power Station (in the former Soviet Union, now Ukraine). Of the 200 people who were exposed to large doses of radiation, 13 severely affected patients whose estimated dose had ranged from 5.6 to 13.4 Gy, received bone marrow transplants by a

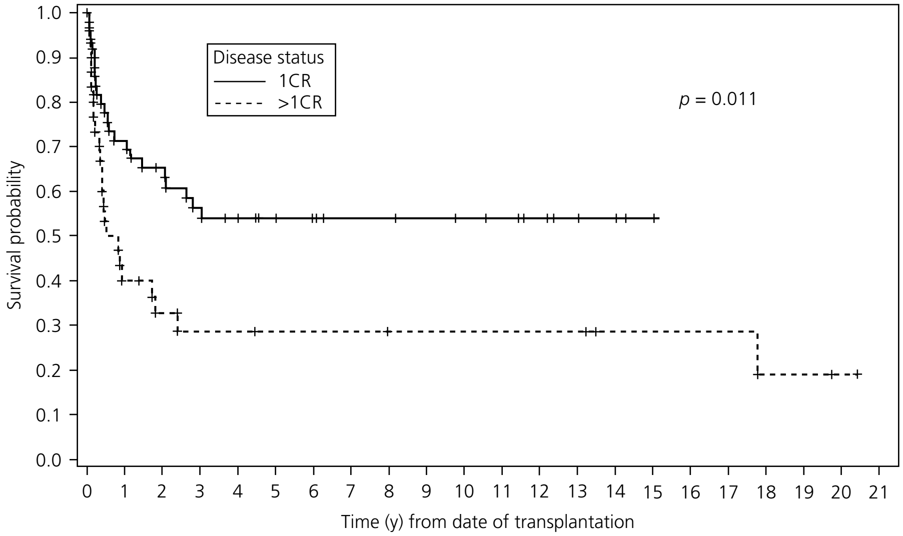

Figure 1.2 Survival of 79 patients with Philadelphia chromosome positive acute lymphoblastic leukemia who received high-dose total body irradiation and etoposide followed by allogeneic HCT from HLA-matched sibling donors. At the time of transplantation, 49 patients were in first complete remission and 30 patients were beyond first remission. The outcome is significantly better for patients who were transplanted earlier compared to those who had suffered at least one relapse prior to HCT. Source: Laport et al. 2008 [45]. Reproduced with permission of the American Society of Hematology.

team of physicians and scientists from the Soviet Union, the United States of America, and Israel. There was hematopoietic recovery in nine patients, six of whom had transient partial engraftment before they recovered their autologous marrow function. Eleven of the transplant recipients died from various causes, including extensive burns, interstitial pneumonitis, GVHD, renal failure, and adult respiratory distress syndrome. Two patients whose radiation doses had been 5.6 and 8.7 Gy, respectively, were alive after 3 years following the radiation accident. It is clear from this experience that bone marrow recovery does not necessarily ensure survival [62].

1989–1999: Progress in the prevention and therapy of CMV disease. New sources of grafts for allogeneic HCT

The introduction of a new antiviral drug, ganciclovir, made it possible to control and reverse infections with CMV, a complication which until then had caused a fatal post-transplant infection in about 15% of HCT recipients. This major accomplishment was demonstrated in two independent, concomitantly performed phase III trials [63,64]. At the same time, new and powerful molecular tests were developed which were based on the polymerase chain reaction principle. These non-invasive tests allowed the rapid and non-invasive monitoring of CMV presence and progression of this viral infection in HCT recipients [65,66].

The knowledge that hematopoietic cells are present in circulating blood, the arrival of cloned growth factors such as the granulocyte colony-stimulating factor (G-CSF) and the availability of apheresis techniques allowed the wide application of collection methods for blood-derived grafts for allogeneic HCT. Three simultaneously published reports documented prompt and durable hematologic reconstitution by such “peripheral” grafts from histocompatible sibling donors [67–69].

Cord blood, another important new source for allogeneic HCT, was introduced by Gluckman et al. [70]. Cord blood registries and banks were developed with national and international participation and have facilitated the use of such grafts into a widely used source for transplantation, especially for pediatric patients.

At the same time, registries of volunteer donors continued to grow, leading to an increased successful use of unrelated donor transplants for patients who were lacking suitably matched related donors [71,72]. This progress was made possible through the continued improvement of molecular tissue typing methods which eventually replaced the conventional serologic typing techniques developed during earlier decades [73–75]. Finally, successful crossing of the HLA barrier became possible allowing HCT from haplotype-matched related donors [76,77].

2000–present: Reduced intensity regimens (RIC) allow transplantation of elderly and medically infirm patients. Hematologic grafts induce tolerance for solid organ transplantation

It had been recognized since the early days of experimental and clinical HCT that a graft-versus-malignancy effect contributes to a major extent to the prevention of post-transplant relapse of the underlying malignancy. Moreover, donor lymphocyte infusions were shown to lead to eradication of recurrent diseases, especially in patients with CML [78,79]. The concept of adoptive immunotherapy was pursued in murine and canine models leading to clinical protocols [80–84]. Countless modifications of reduced intensity regimens have been developed over the past decade, some containing low-dose total body irradiation plus chemotherapy and others consist of combinations of various drugs. The use of these rather non-toxic preparatory regimens has allowed the use of HCT for older patients or those with comorbid conditions who previously had not been considered suitable transplant candidates. It was demonstrated in a large group of 372 uniformly treated patients who were between 60 and 75 years old that age is no longer a barrier to successful allogeneic HCT [85]. These RIC transplant procedures can be performed most often on an outpatient basis and require only infrequent transfusional support. The need for immunosuppressive drugs is similar to that in patients prepared with high-dose preparatory regimens [86].

After several decades of extensive pre-clinical research in mice, investigators were finally able to utilize the experimental principle first described by Main and Prehn [11], and by Mannick et al. [22], that is, the induction of tolerance for solid organ transplantation by the administration of donor hematopoietic cells [87,88]. In a recent series of 16 patients with end-stage renal disease who were conditioned with total lymphoid irradiation and anti-thymocyte globulin, kidney transplants and hematopoietic cells enriched with T cells from HLA-matched donors were administered [89]. Fifteen patients developed multi-lineage chimerism without GVHD. It was possible to discontinue all immunosuppression in eight patients who have now been followed off medications for 16–40 months, four patients have just completed or are in the midst of drug withdrawal, and four patients were not withdrawn due to return of their underlying renal disease or because of rejection episodes. At the last observation point, all 16 patients had an excellent kidney graft function with or without maintenance drugs [89].

History of autologous HCT

1958–1964: From pre-clinical studies to first clinical transplant efforts

The concept of storing autologous hematopoietic cells while patients are being exposed to high doses of irradiation and/or high-dose cancer drugs with subsequent cell reinfusion was developed over half a century ago. The initial studies were performed in canine or murine models [25,90–96]. First, glycerol was used to protect hematopoietic cells from the destructive effects of freezing and thawing, later dimethyl sulfoxide was successfully employed as a cryoprotectant and is still the preferred chemical agent for this purpose. Storage of marrow cells without cryopreservation was also shown to be possible. However, with preparatory regimens becoming more complex and more time-consuming to administer, cryopreservation of hematopoietic cells evolved into the generally accepted storage technology.

In the beginning, preparatory regimens for clinical use contained mostly high-dose irradiation and/or alkylating drugs (nitrogen mustard or cyclophosphamide). The first series of autografted patients were reported between 1959 and 1962 [97–100]. Hematopoietic function was restored in most of these patients and transient tumor responses were frequently observed, mostly in patients with non-Hodgkin or Hodgkin lymphoma.

1978–1995: The beginning of an era of promising results in autologous HCT

With reliable cryopreservation methods for storage of bone marrow cells and an increasing number of drugs becoming available, investigators began to explore combinations of dose-escalated anticancer agents [101]. In 1978, Appelbaum and colleagues [102,103] described their experience with the quadruple combination of carmustine, cytarabine, cyclophosphamide and thioguanine followed by autografting in patients with non-Hodgkin lymphoma. Transplanted patients recovered their blood counts significantly faster than control patients and several of the transplant recipients entered durable remissions and were apparently cured of their lymphoma.

Another drug combination of cyclophosphamide, carmustine, and etoposide [104] was tested successfully in patients with Hodgkin lymphoma and has become a widely employed regimen, sometimes cytarabine is added as a fourth drug. This regimen was modified by replacing cyclophosphamide with melphalan and is now widely used at transplant centers around the world, especially for patients with lymphoid malignancies.

A pivotal clinical study was performed by Philip and colleagues which became known as the PARMA trial. The investigators succeeded in their efforts to compare the outcome of autologous HCT to conventional chemotherapy in non-Hodgkin lymphoma patients: HCT recipients attained significantly superior event-free survival compared to the conventionally treated group [105], see Figure 1.3.

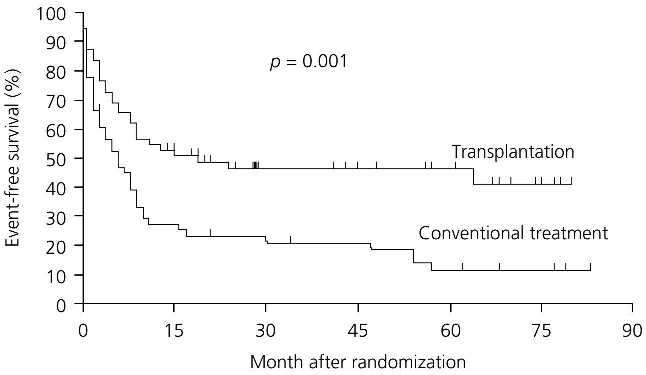

Figure 1.3 Actuarial event-free survival of patients with non-Hodgkin lymphoma treated on the PARMA trial. In this clinical study, the outcome of autologous HCT was compared prospectively to conventional dose chemotherapy. The shown data are based on an intent-to-treat analysis. Source: Philip et al. 1995 [105]. Reproduced with permission of the Massachusetts Medical Society.

Autologous transplantation for the acute leukemias was also actively explored, ultimately leading to a series of prospective clinical trials in which standard dose chemotherapy was compared to high-dose regimens followed by autologous HCT. The data unfortunately show rather inconsistent results with highly positive studies conflicting with negative outcomes data from other trials. New regimens have been developed for patients with acute myeloid leukemia, for example, the high-dose busulfan-etoposide regimen which is well tolerated and has led to promising results that are now being tested under cooperative group conditions [106–108].

1986–2004: Circulating stem cells and cloned hematopoietic growth factors

It was known from earlier studies in mice [24], dogs [109], and baboons [110] that cells from circulating blood could restore bone marrow function in lethally irradiated animals. The use of multiple apheresis procedures allowed the successful clinical use of autologous grafts [111]. Initial approaches to increase the number of stem cells in the peripheral blood included the administration of small amounts of endotoxin [112]. Other investigators exploited the rebound effect on the release of stem cells from bone marrow in patients recovering from chemotherapy [113,114]. However, major progress had to wait for the introduction of cloned hematopoietic growth factors, the granulocyte–macrophage colony-stimulating factor (GM-CSF) and the already mentioned factor, G-CSF [115–117]. Over time, it became a standard approach to administer cyclophosphamide followed by G-CSF or G-CSF alone and apheresis for the collection of autologous hematopoietic grafts. The presence of peripheral blood stem cells can be monitored by measuring $CD34^+$ cells as a surrogate marker. Between 2 and 5 million $CD34^+$ cells/kg body weight of the recipient are considered an adequate number of “stem cells” to proceed to transplantation. The question of which is the preferred source for an autologous graft, bone marrow or peripheral blood, has been answered, at least in the treatment of lymphoma, by two appropriately designed clinical trials which both showed the superiority of the graft collected by apheresis [118,119]. The criteria for speed of restoration were the recovery from white blood cell and platelet nadirs which has resulted in lower morbidity and mortality following autologous HCT. Patients who mobilize "stem cells" poorly can still respond favorably to a new CXCR4 antagonist [120].

1982–2001: Testing for minimal residual disease and efforts to "purge" grafts for autologous HCT

It was – and still is – a serious concern that autologous cell collections aspirated from the marrow cavity or collected from blood by apheresis contain tumor cells which – if clonogenic – may contribute to relapse of the underlying malignancy. The presence of tumor cells in cell collections was demonstrated by immunohistochemistry, bone marrow cultures, and by molecular methods [121–124]. Gene-marking studies performed by Brenner and colleagues [125] indicated that such marked cells were detectable in the patient at the time of relapse after autologous transplantation.

Tumor cell "purging" was attempted and clinically tested in multiple graft engineering laboratories around the world. Methods for *negative* selection employed immunologic, as well as pharmacologic principles: monoclonal antibodies (mAb) with complement, mAbs conjugated to magnetic beads, or toxins or drugs, or drugs only, such as 4-hydroperoxycyclophosphamide or mafosfamide [126–142]. Still other investigators developed and tested devices such as columns to separate tumor cells from marrow aspirates or from blood concentrates collected by apheresis [143–147].

Positive stem cell isolation techniques were pursued in mice and humans [148,149] and such highly purified cell preparations were administered to patients after they had received high-dose irradiation or combination chemotherapy [150–153]. A few stage IV breast cancer patients who were autografted with these cell preparations have become long-term survivors and are in continued complete remission more than a decade after their transplant procedure [154].

The diseases in which the different negative and positive selection methods were used included non-Hodgkin lymphoma, acute myeloid leukemia, acute lymphoblastic leukemia, multiple myeloma, neuroblastoma, and breast cancer. Well-designed, large prospective trials to prove convincingly the superiority of "purged" grafts are unfortunately missing from the clinical scientific literature.

1986–1999: High-dose chemotherapy and transplantation of autologous hematopoietic cells for patients with breast cancer

Initially, high-dose chemotherapy and autologous transplantation was tested in women who had stage IV breast cancer. Tumor responses were attained in some patients, however, these favorable reactions were only transient. During the 1990s, several high-dose regimens were established in large cancer treatment centers and were soon used worldwide in women with stage II or stage III breast cancer [155,156]. This approach to breast cancer was so frequently employed that in 1994–1995, about 40% of all autologous transplant procedures were performed in patients with breast cancer. This rapid increase in use of the procedure was not based on any solid data from appropriately designed phase III trials. Several prospective trials were done concomitantly during the last decade of the twentieth century. In 1999, the first reliable interim analyses of several comparative studies indicated that no survival benefit was to be expected and the use of autologous transplantation for breast cancer plummeted. A subsequent meta-analysis of 15 randomized trials of 6102 patients with high-risk disease detected a significant advantage with respect to event-free survival, but the difference in overall survival at 5 years after transplantation did not reach statistical significance [157]. Earlier, a clinical phase III study had indicated equivalence in outcome of autologous HCT compared to conventional chemotherapy in patients with metastatic breast cancer [158]. Finally, the revelation of scientific fraud [159,160] in the reports on positive clinical trials from one center [161] led to a dramatic reduction of HCT worldwide for the treatment of women with breast cancer.

1993–present: Research to improve preparatory regimens and efforts to consolidate post-HCT remissions

The single purpose of the preparatory regimen in autologous HCT is the permanent eradication of tumor cells: the goal of this step is the induction of a durable remission, that is, cure. However, relapse of the underlying disease is the major cause for treatment failure. Therefore, investigators have attempted to intensify the pretransplant regimens by further dose escalation of drugs already established for this purpose, or by adding new agents to existing high-dose combinations. Alternatively, investigators have explored high-dose sequential therapies with infusion of autologous hematopoietic cells after each treatment cycle [162]. Dose-limiting for all these efforts were toxicities to vital, non-hematologic organs such as liver, lung, heart, and the central nervous system.

Another rather elegant – because more targeted – approach is the incorporation of radio-labeled mAbs into preparatory regimens which has been done successfully for patients with non-Hodgkin lymphoma [163–165]. Unfortunately, these promising technologies are not yet widely used, mostly due to the need for experienced nuclear medicine specialists and rather sophisticated equipment.

Finally, the option to consolidate the transplant-induced complete remission with immunologic techniques has been actively pursued. For this purpose, cytokines (interleukin-2 or interferon) mAbs, irradiation to areas of prior "bulk" disease, idiotype vaccines or "educated" autologous cells such as cytokine-induced killer cells have been employed. These studies were mostly performed as clinical feasibility trials. However, the data following the use of rituximab after autologous HCT for non-Hodgkin lymphoma are impressive [166] and long-term disease-free survival at a high rate has been attained [167], see Figure 1.4.

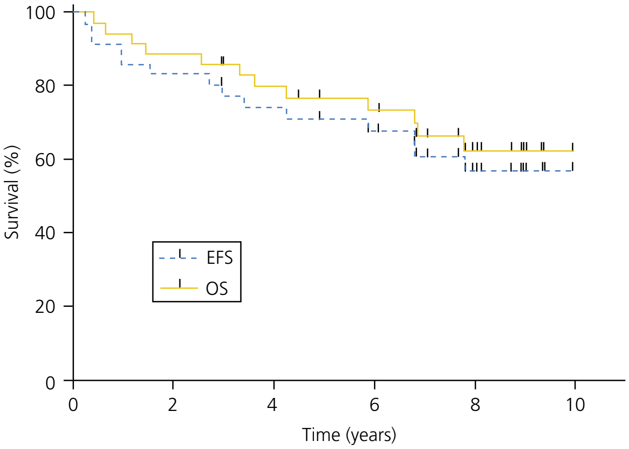

Figure 1.4 Kaplan–Meier estimates of event-free survival (EFS) and overall survival (OS) of 35 patients with recurrent or refractory B-cell lymphoma. These patients received autologous transplants and were given two courses of rituximab (4 weekly infusions, 6 weeks and 6 months following transplantation). Source: Weng et al. 2010 [167]. Reproduced with permission of the American Society of Clinical Oncology.

Conclusion

What has been accomplished in the field of allogeneic and autologous HCT during a half century of intense pre-clinical and clinical research? The answer to this question is: Long-term disease-free survival and cure in a substantial number of patients. Forty years ago, survival of our patients was measured in “days after transplantation” while now disease-free survival is expressed in years – or even – decades after HCT. In 2012, the 1,000,000th patient received a hematopoietic cell transplant (source: M.M. Horowitz, Center for International Blood and Marrow Transplant Research; see also Chapter 2 of this book). That means that 1,000,000 children, adolescents, and adults whose life expectancy was rather limited because of a serious disease were offered a chance for cure. This does not mean that all problems surrounding HCT have been solved during the past decades. Table 1.1 lists the problem areas and obstacles to success which patients and physician-investigators faced when transplantation became a treatment reality in the 1960s. A review of the list of problems in 2012 indicates that remarkable progress has been made in all areas:

1. It is now possible to offer HCT to older and medically infirm patients.
2. Through intense national and international efforts, the large number of volunteer donors and cord blood concentrates make it now possible to offer HCT to many patients who are lacking a suitably matched related donor.
3. Efforts to reduce extramedullary toxicities have been largely successful, especially through the introduction of reduced intensity regimens for allogeneic HCT and many transplant recipients never require admission to the hospital.
4. Graft failure is now a rare event because of (a) better tissue typing methods to identify the most suitably matched donor, and (b) the ability to mobilize and collect sufficient cells for autologous HCT.
5. Great strides have been made through preemptive therapy of cytomegalovirus infections. Potent new antibiotics and better antifungal agents have been introduced.
6. The greatest obstacle in allogeneic HCT remains graft-versus-host disease; however, potent immunosuppressive drugs have been developed and successfully added to our armamentarium.
7. Resistant malignant cells are difficult to eliminate and may lead to a relapse of the former disease after allogeneic or autologous HCT. On the other hand, harnessing the graft-versus-tumor effect is becoming increasingly possible and may be regularly attainable without GVHD in the near future.
8. Long-term observations have revealed the risk of new malignancies occurring after HCT. But we should also keep in mind that all treatments following the original diagnosis of cancer have a cumulative effect toward second malignancies, that is, it is not just the transplant effort which is the sole cause for new cancer.
9. Another painful lesson was learned from years and even decades of follow-up of HCT recipients who over time have developed heart, lung, and kidney diseases, as well as diabetes mellitus at a significantly higher rate than age-matched controls.
10. Many carefully performed studies have demonstrated that the quality of life of our patients is fortunately quite good. By far the majority of them consider the step to proceed to HCT as a very positive decision in their life.
11. Cost and charges for HCT are stunning as they are extremely high in most parts of the world. Leaders in hospital administrations should be urged constantly to use their best judgment pertaining to reasonable pricing of medical procedures.
12. Here is a final message from the authors of this chapter to all young readers, colleagues, and investigators in the field: Persistence in high-quality clinical research has allowed hematopoietic cell transplantation to become a procedure which can be widely offered with curative intent and curative potential. Transplantation of blood-forming cells will continue to evolve and develop. The future of HCT is really bright!

Table 1.1 Problem areas of allogeneic and autologous hematopoietic cell transplantation. Problems are listed in chronological order as they occur in the course of the respective transplant procedure

Allogeneic	Autologous
Age limit	Age limit
Availability of a suitable donor	Regimen-related toxicity
Regimen-related toxicity	Graft failure
Graft failure/rejection	Opportunistic infections
Opportunistic infections	Relapse
Graft-versus-host disease	New malignancies
Relapse	Long-term health problems
New malignancies	Quality of life issues
Long-term health problems	Cost/charges
Quality of life issues	
Cost/charges

CHAPTER 2

Uses and Growth of Hematopoietic Cell Transplantation

Mary M. Horowitz
Froedtert and the Medical College of Wisconsin, Milwaukee, WI, USA

Introduction

The first successful transplantations of allogeneic hematopoietic cells were performed in 1968 in three children with congenital immune deficiency diseases [1–4]. In each instance, hematopoietic cells were collected from the bone marrow of sibling donors who were genotypically identical or closely matched to the recipient for human leukocyte antigens (HLAs). Since then, more than 1,000,000 patients have received hematopoietic cell transplantations (HCTs) to treat life-threatening malignant and nonmalignant diseases. Current estimates of annual number of HCTs are 55,000–60,000, worldwide (Figure 2.1). Reasons for widespread use include proven and potential efficacy in many diseases, better understanding of the appropriate timing of transplantation and patient selection, greater availability of donors, greater ease of hematopoietic progenitor cell collection, and improved transplantation strategies and supportive care, leading to less transplantation-related morbidity and mortality and an increased ability to perform the procedure in older and sicker patients.

Changing indications for HCT

HCT has efficacy in many diseases (Table 2.1). In some, transplantation corrects congenital or acquired defects in blood cell production and/or immune function. In others, it restores hematopoiesis after high-dose (myeloablative) cytotoxic therapy for malignancy and/or provides potent anticancer adoptive immunotherapy. In the 1970s, more than half of the HCTs were performed for nonmalignant disorders: 40% were for aplastic anemia and 15% for immune deficiencies. Fewer than half were for cancers, and these were mostly for advanced acute leukemia. In the 1970s, Thomas and colleagues showed convincingly that some patients with refractory acute leukemia could achieve long-term leukemia-free survival with high-dose therapy and HLA-identical sibling marrow transplantation (see Chapter 1) [5,6]. Better outcome was subsequently demonstrated in patients transplanted in first or second remission [7–9]. Syngeneic (identical twin) and allogeneic HCTs were shown to produce cytogenetic remissions and long-term leukemia-free survival in chronic myeloid leukemia (CML) in the late 1970s and early 1980s [10–12].

Use of allogeneic HCT to treat leukemia increased dramatically in the 1980s. By 1985, about 75% of allogeneic transplantations were for leukemia, with approximately equal numbers for CML, acute myeloid leukemia (AML), and acute lymphoblastic leukemia (ALL); more than 90% were from HLA-identical sibling donors. Introduction of alternative targeted therapies for CML in the early 2000s led to decreased use of HCT, with current guidelines reserving HCT for patients who fail to respond to non-transplant therapy or who lose their response [13]. However, leukemia treatment still accounts for about 65% of allogeneic HCT procedures (Figure 2.2) (Center for International Blood and Marrow Transplant Research (CIBMTR) Statistical Center, unpublished data).

Experimental and clinical evidence for a dose–response effect of drugs used in lymphoma therapy led to trials of autologous HCT to allow dose intensification in non-Hodgkin lymphoma in the middle 1980s (see Chapter 1) [14–16]. Results were promising, and there was rapid acceptance of autologous transplantation as salvage therapy in persons failing conventional chemotherapy for lymphoma. This was followed by increasing use of autologous transplantation as consolidation of primary therapy in patients with high-risk disease. There is now more frequent use of allogeneic transplantation in lymphoma to harness immune-mediated graft-versus-lymphoma effects, especially in patients whose disease recurs after autologous transplantation, and in patients with follicular histology who are rarely cured by autologous transplantation [17]. Lymphoma accounted for 10% of allogeneic HCTs in 2011 (CIBMTR Statistical Center, unpublished data).

The rationale of dose intensification led to the application of high-dose therapy with autologous transplantation to many other hematologic and nonhematologic cancers over the past 10 years. One striking development was a dramatic increase in their use for breast cancer in the early 1990s. Breast cancer accounted for 16% of autologous transplants carried out in 1989–1990 and 40% in 1994–1995 [18]. However, results of randomized clinical trials in early and advanced breast cancer were disappointing (reviewed in [19–21]). In 1999, the use of HCT for breast cancer declined dramatically, and in 2011 breast cancer accounted for fewer than 5% of autologous transplants in North America. Treatment of solid tumors, primarily neuroblastoma and testicular cancer, still accounts for 5–10% of autologous transplants (Figure 2.2).

In 1996, results of a randomized trial comparing high-dose therapy and autologous HCT with conventional therapy for multiple myeloma were published; this study found a significant survival benefit with autologous transplantation [22]. Autologous HCT for myeloma increased dramatically after this report. Subsequent data suggested improved results with sequential autologous transplantations or autologous transplantation followed by allogeneic transplantation [23,24]. Multiple myeloma is now the single most

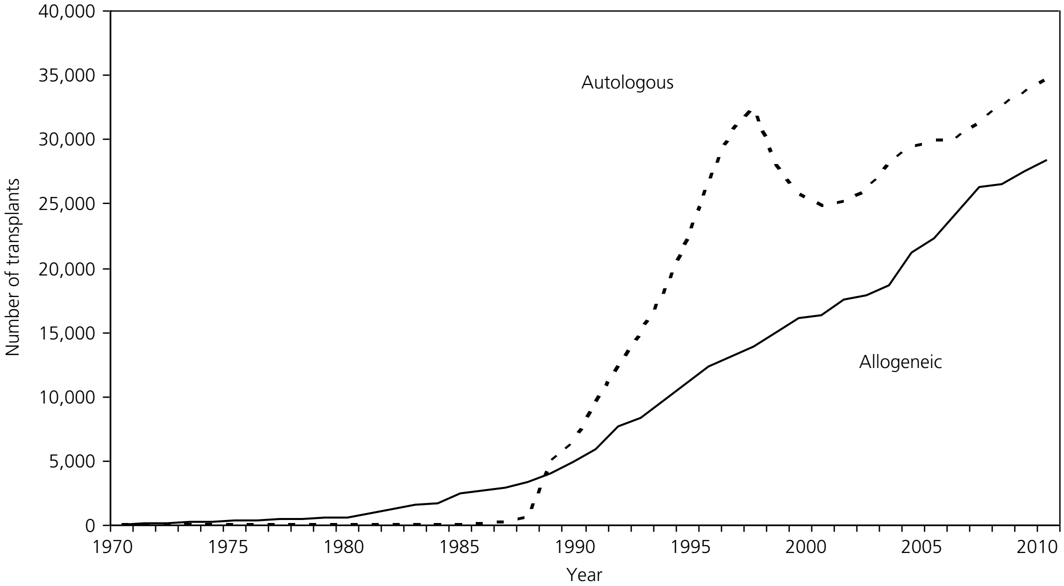

Figure 2.1 Numbers of allogeneic and autologous hematopoietic cell transplantations performed yearly worldwide. Data from the CIBMTR Statistical Center.

Table 2.1 Diseases in which autologous and/or allogeneic hematopoietic cell transplants may be used

Malignant	Nonmalignant
Leukemia/preleukemia	Severe aplastic anemia
Chronic myeloid leukemia	Paroxysmal nocturnal hemoglobinuria
Myeloproliferative syndromes (other than chronic myeloid leukemia)	Hemoglobinopathies
Acute myeloid leukemia	Thalassemia major
Acute lymphoblastic leukemia	Sickle cell disease
Juvenile chronic myeloid leukemia	Congenital disorders of hematopoiesis
Myelodysplastic syndromes	Fanconi anemia
Therapy-related myelodysplasia/leukemia	Diamond–Blackfan syndrome
Kostmann's agranulocytosis	Familial erythrophagocytic histiocytosis
Chronic lymphocytic leukemia	Dyskeratosiscongenita
Non-Hodgkin and Hodgkin lymphoma	Shwachman–Diamond syndrome
Multiple myeloma	Severe combined immune deficiency and related disorders
Solid tumors	Wiskott–Aldrich syndrome
Breast cancer	Inborn errors of metabolism
Neuroblastoma	Acquired autoimmune diseases
Sarcomas	
Ovarian cancer	
Small cell lung cancer	
Testicular cancer	

common indication for HCT, accounting for 50% of autologous transplants but fewer than 5% of allogeneic transplants (Figure 2.2). Although 30% of HCTs for myeloma in 2006 involved a planned autologous–autologous or autologous–allogeneic transplant approach, this strategy is currently controversial and only about 10% of HCTs for myeloma in 2011 involved a sequential approach (CIBMTR Statistical Center, unpublished data) [25]. The role of planned second transplants decreased to about 10% in 2011 and remains controversial [25].

The most common indications for allogeneic and autologous HCT in North America in 2011 are shown in Figure 2.2. About 75% of allogeneic HCTs are for leukemia or myelodysplasia: 37% for AML, 16% for ALL, 4% for CML, 14% for myelodysplastic or myeloproliferative syndromes, and about 5% for other leukemias. Eleven percent are for other cancers, including non-Hodgkin lymphoma (9%), multiple myeloma (<5%), Hodgkin disease (<5%), and other cancers (<5%). The remainder are for aplastic anemia (5%), immune deficiencies (<5%), and other diverse nonmalignant disorders. The most common indications for autologous transplants are multiple myeloma (50%), non-Hodgkin lymphoma (28%), Hodgkin disease (10%), leukemia (<5%), neuroblastoma (<5%), and other cancers (CIBMTR Statistical Center, unpublished data).

There is increasing interest in using HCT in several diseases where transplantation was not or was rarely used in the past, some with promising results in either anecdotal reports or phase II studies. These include sickle cell disease (see Chapter 73), inborn errors of metabolism (see Chapter 75), chronic lymphocytic leukemia (see Chapter 60), solid tumors such as ovarian, renal cell, and small cell lung cancer (see Chapter 63), and autoimmune diseases such as multiple sclerosis, systemic lupus erythematosus, systemic sclerosis, and severe rheumatoid arthritis (see Chapter 67). Taken together, these diseases currently account for fewer than 10% of HCTs, whether allogeneic or autologous, up from fewer than 5% five years ago. Several large trials of HCT for autoimmune disease are being conducted in Europe and in the United States. The prevalence of these diseases is high and, if trials confirm efficacy, the numbers of persons considered for HCT could increase dramatically. Hematopoietic cells are also ideal candidates as vehicles for gene therapy, and their use in this capacity is being explored in several settings (see Chapter 8). Finally, hematopoietic stem cells are now being used for the regeneration of non-hematopoietic tissues, including myocardium and nerves, in some phase I and II studies [26].

Changes in patient selection

In the 1970s, marrow transplants were often applied as desperate measures for desperate situations. Not infrequently, patients came to transplantation with longstanding, refractory cancers, with active infection, after receiving multiple transfusions, and with poor performance status.

The available drugs for prophylaxis of graft-versus-host disease (GVHD) were not optimal, nor were supportive care measures, especially antiviral and antifungal therapy. Not surprisingly, these procedures were associated with high risks for graft failure, GVHD,

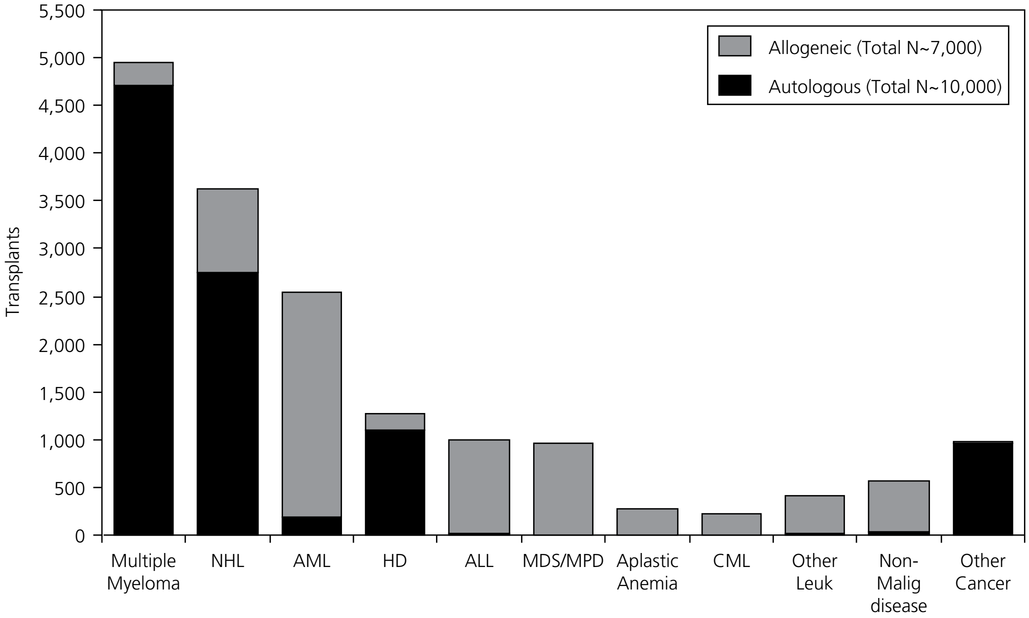

Figure 2.2 Indications for hematopoietic cell transplantation in North America, 2011. ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CML, chronic myeloid leukemia; MDS/MPS, myeloproliferative disorder/myelodysplastic syndrome; NHL, non-Hodgkin lymphoma. Data from the CIBMTR Statistical Center.

infectious and non-infectious pneumonitis, non-pulmonary infections, and other complications, all leading to high transplant-related mortality. Much of the acceptance and growth of transplantation is attributable to a better understanding of factors leading to improved transplantation outcomes, especially selection of appropriate patients for transplantation at a point in their disease course when transplantation is most likely to be of benefit. Many studies in diverse diseases demonstrate that HCTs done earlier are associated with lower risks of both transplant-related mortality and disease recurrence.

Transplantation is now commonly applied as first- or second-line rather than "last chance" therapy. In the 1970s, only 20% of HLA-identical sibling HCTs for acute leukemia were carried out in first remission, while 60% were done for advanced disease (not in remission or in a third or subsequent remission). In contrast, in 2011, about 60% of HCTs for acute leukemia were done for patients in first remission, 20% in second remission, and only 20% for advanced disease (CIBMTR Statistical Center, unpublished data). Although delay beyond first remission may be appropriate for patients with standard-risk ALL or good-risk AML (who may have good outcomes with conventional therapy), most young patients with AML are probably best served by allogeneic transplantation carried out soon after diagnosis if a suitably matched donor, related or unrelated, is available. Such a strategy is not only associated with better outcome, but also decreases the chance that patients will develop an intervening complication (refractory relapse, life-threatening infection, or organ toxicity) that will preclude transplantation.

There has also been a trend for earlier use of autologous transplants. In 1989, the median interval between diagnosis and autologous transplantation for non-Hodgkin lymphoma was 23 months; in 2011, it was 14 months (CIBMTR Statistical Center, unpublished data). Similarly, in 1990, the median interval between diagnosis and autologous transplantation for multiple myeloma was 18 months; in 2011, it was 8 months. This change is attributable largely to the demonstration of efficacy of autologous transplantation as part of primary treatment or as first salvage therapy (see Chapters 56–59) for myeloma and lymphoma, leading to use earlier in the course of these diseases.

Earlier treatment accounts, in part, for the fact that patients in 2011 were less likely to have poor performance status at the time of transplantation than were patients in the 1970s. About 40% of patients transplanted in 1974–1979 had pretransplant Karnofsky scores of less than 80%, compared with 10% in 2011 (CIBMTR Statistical Center, unpublished data).

HCT is now used in much older patients than in the 1970s, when the median age of transplant recipients was 17 years and fewer than 5% were older than 40 years. In 2006, the median age of allograft recipients was 39 years, and of autograft recipients 56 years; in 2011, the corresponding figures were 47 and 56 years (CIBMTR Statistical Center, unpublished data). This is important since the diseases for which HCT is most frequently applied have their onset in older adulthood, often in the sixth decade. The ability to apply HCT in older patients makes it a useful treatment for many more patients. Autologous transplants have been successfully used in patients older than 70 years. Eighty-two percent of autologous transplant recipients in 2011 were over the age of 40 years, and 41% were older than 60 years. Allogeneic HCT is also being used in older patients, with the introduction of better GVHD prophylaxis, less toxic conditioning, and improved supportive care. Fifty-nine percent of allograft recipients in 2011 were older than 40 years, in contrast to only 28% in 1995. Forty-five percent of the allogeneic HCTs carried out in 2011 were in patients older than 50, and 20% were in patients older than 60 years. Several studies suggest that, among adults over the age of 30, increasing age has only modest effects on transplantation outcome, at least up to the age of 50 [27,28].

One recent approach to increase use of allografts in older adults is reduced-intensity or non-myeloablative conditioning. This strategy uses conditioning as immunosuppressive therapy to allow donor cell engraftment rather than as high-dose anticancer therapy. The approach relies on immune-mediated graft-versus-tumor effects for long-term disease control (see Chapter 21). First reported in the late 1990s, transplants using reduced-intensity conditioning now account for about 35% of allografts registered with the CIBMTR and 60% of allografts in patients over the age of 55 years. Data on long-term outcome or efficacy relative to conventional HCT are still lacking. A large randomized trial of high versus reduced intensity conditioning for patients receiving HLA-identical sibling or unrelated donor transplantation for AML or MDS is currently being conducted by the Blood and Marrow Transplant Clinical Trials Network.

Hematopoietic cell sources

In the 1970s and early 1980s, essentially all HCTs used cells collected from the marrow of closely HLA-matched related donors. The few transplantations done with HLA-mismatched related donors were associated with high risks of graft failure, GVHD, and poor outcome, except, in some series, when the disparity was limited to a single HLA antigen [29,30]. This limited application of HCT to the 25–30% of patients with an HLA-matched relative. Several developments dramatically increased the applicability of HCT to patients without HLA-identical relatives, including the use of autologous cells, collection of cells from blood rather than marrow, and use of unrelated donors.

Autologous transplantation

Although a few autologous transplantations were carried out before the 1970s, the approach of collecting cells from a patient before high-dose therapy with reinfusion afterwards did not generate much enthusiasm until the middle to late 1980s (see Chapter 1) [31]. The appeal of the approach rested in its applicability, since it did not require a donor, allowing dose intensification with hematopoietic cell support in many patients with chemotherapy-sensitive cancers. Autologous transplants were also associated with lower transplant-related mortality since GVHD did not occur and immune recovery was more rapid than after allografting. Although immune-mediated antitumor effects were also absent, and there was some concern about reinfusing cancer cells with the graft, early trials showed good results in persons with lymphomas failing other therapies. The technology diffused rapidly in the late 1980s, becoming the treatment of choice for those with relapsed lymphoma and increasingly used for other chemotherapy-sensitive but infrequently cured cancers, including acute leukemia, multiple myeloma, and selected solid tumors.

An important development allowing diffusion of the technology was the demonstration that hematopoietic cell grafts could be collected from peripheral blood in a limited number of leukaphereses after mobilization with chemotherapy or growth factors such as granulocyte- or granulocyte/macrophage-colony stimulating factor [32–34]. The resulting hematopoietic cell products contained large numbers of progenitor cells and led to faster hematopoietic recovery after transplantation. It also eliminated the need for a marrow harvest in an operating room. Whereas in 1989–1990, 85% of autologous transplants used cells collected from marrow, by 2000 fewer than 5% used marrow cells alone (CIBMTR Statistical Center, unpublished data). In contrast to allogeneic transplantations, many of which are still done in academic, tertiary care medical centers, autologous transplants were soon used in the community setting, partly because of the ease with which the hematopoietic cell product could be obtained, and partly because of the more rapid hematopoietic and immune recovery and lower frequency of transplant-related complications compared with allografting. This likely increased the numbers of patients offered HCT.

Allogeneic transplantation

There were anecdotal reports of successful HCTs using HLA-matched unrelated donors as early as 1973 [35–37], but the polymorphism of human HLA made the feasibility of finding such a donor for an individual patient low. In the middle 1980s, several national and international groups organized marrow donor registries with panels of HLA-typed volunteers agreeing to serve as donors for unrelated patients. There are about 20 million HLA-typed volunteer donors worldwide (see Chapter 37). Accessing these donors is facilitated by their listing in a compendium by Bone Marrow Donors Worldwide (www.bmdw.org), a collaborative effort of many national registries coordinated by the Europdonor group (www.europdonor.org), and by rapid computerized searching made available by several national and international registries. The largest donor registry is the US National Marrow Donor Program (NMDP; www.marrow.org), which has about 11 million donors on its file. The NMDP also has a web-based search application available for patients to perform a preliminary search (MatchView^{sm}) and has implemented an application, Haplogic^{TM}, to assist transplant physicians in estimating the probability of finding a fully matched unrelated donor for an individual patient.

Currently, Caucasian patients have a 70% or greater chance of finding a donor that is matched at high-resolution typing for HLA-A, B, C, and DRB1 through existing donor panels. Because of greater HLA polymorphism and fewer ethnically similar donors, patients in other groups have lower probabilities of finding an HLA-matched unrelated donor, but 50–70% will find a donor mismatched at only one of these loci, which may afford an acceptable if not optimal alternative [38].

The establishment of large donor panels dramatically increased the use of unrelated donor transplantation. While in 1985 fewer than 10% of allogeneic HCTs were from unrelated donors, in 2011 more than 40% were from unrelated donors. Unrelated donor transplantation accounted for much of the growth of HCT in the United States over the past decade (Figure 2.3). In some settings, survival after unrelated donor transplantation is similar to that after HLA-identical sibling transplantation, although the risks of graft failure and GVHD are higher (see Chapter 46). Unrelated donor HCT is associated with longer delays between diagnosis and transplantation, partly because of the time needed for the donor search and evaluation process. Delays are caused by reluctance on the part of some physicians to use what has historically been a more difficult transplantation approach early in disease. Recent data, however, suggest that HLA-matched unrelated donor transplantation should be considered whenever HLA-identical sibling transplantation is indicated [39].

As recently as 2002, most allogeneic HCTs used cells collected from marrow. For many years, there was reluctance to use cells collected from peripheral blood because of the large numbers of mature T lymphocytes, the cells that mediate GVHD, in blood-derived grafts. However, in 1995, three centers reported rapid hematopoietic recovery and acceptable acute GVHD after HLA-identical related peripheral blood allografts in a small number of patients [40–42]. A rapid increase in allogeneic peripheral blood HCTs followed. About 75% of related donor and 60% of unrelated donor HCTs now use cells obtained by leukapheresis.

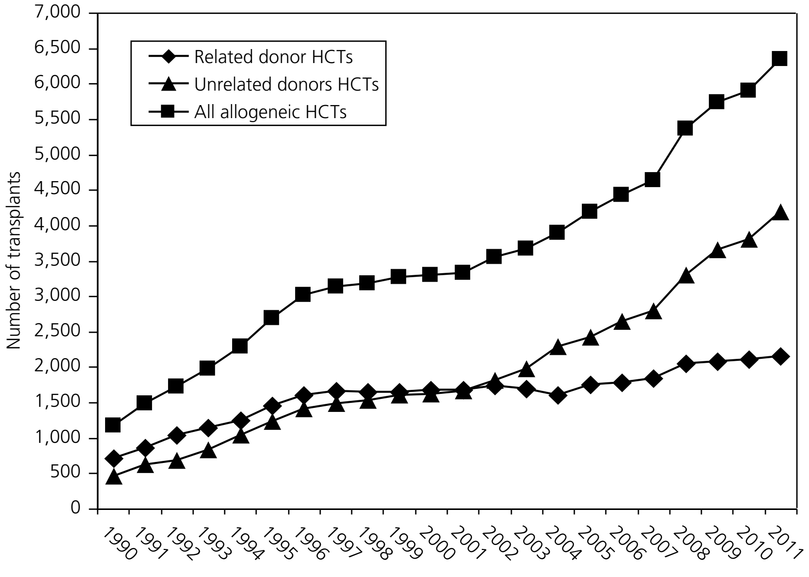

Figure 2.3 Annual numbers of allogeneic hematopoietic cell transplantations (HCTs) in the United States reported to the Center for International Blood and Marrow Transplant Research. Data from the CIBMTR Statistical Center.

Several randomized trials have compared the results of peripheral blood and marrow HCTs in the related donor setting [43,44]. Some, but not all, suggest an early survival advantage with peripheral blood HCT in patients with advanced disease. However, most studies also indicate an increased risk of chronic GVHD, associated in some studies with higher late mortality (see Chapter 42). Data about the relative efficacy of marrow and peripheral blood transplants in the unrelated donor setting are more limited. An observational study of unrelated donor transplant recipients conducted by the CIBMTR and the NMDP suggested that survival was similar, but GVHD more frequent with peripheral blood versus bone marrow grafts [45]. A single large randomized trial, conducted by the US Blood and Marrow Transplant Clinical Trial Network (BMT CTN), has addressed this issue in patients receiving myeloablative conditioning [46]. Among 550 patients randomized to receive blood or marrow grafts from unrelated donors, the probability of survival was virtually identical but graft failure was more common with marrow grafts while extensive chronic GVHD was more common with peripheral blood grafts. Of note, recipients of blood grafts had a 20% higher incidence of remaining on immunosuppression by 2 years after transplantation than marrow graft recipients. Whether this will change the current patterns of graft procurement remains to be seen. Data are still lacking regarding the optimal graft source when using reduced intensity conditioning.

Multiple experimental and clinical studies since the 1990s suggest that umbilical cord blood (UCB), which is rich in hematopoietic progenitors, may be a good source of allogeneic hematopoietic cells for transplantation (see Chapter 39). To be useful, there must be a large supply of cord blood units readily available. Several cord blood banks were established over the past two decades, with more than 500,000 units cryopreserved worldwide in 2012. The advantage of UCB transplantation is rapid availability of a graft without need for screening, typing and collecting cells from live donors, and the potential to target underrepresented ethnic groups for collection and storage. Most clinical data indicate that UCB transplantation has less potential for severe GVHD, even with a substantial degree of donor–recipient HLA mismatch, than adult donor transplants. UCB transplants now account for about 50% of the unrelated donor transplants carried out in children younger than 10 years old.

Hematopoietic recovery after UCB transplantation may be slow, particularly in adults and larger adolescents, in whom the cell dose (cells/kg of recipient weight) may be limiting. Consequently, UCB accounts for only 30% (increased from 20% in 2006) of the unrelated donor transplants done in children 10–19 years of age and only 15% (increased from 5% in 2006) of those in adults 20 years of age and older. However, a growing number of studies in adults have demonstrated the potential success of UCB transplantation [47–50]. Several approaches are being studied to increase the speed and certainty of engraftment. These include use of double UCB grafts, co-infusion of mesenchymal cells, co-infusion of T-cell-depleted haploidentical peripheral blood stem cells, injection of cord blood into the bone marrow directly, and cell expansion using a variety of techniques.

Use of relatives partially matched for HLAs is another way of offering HCTs to more people (see Chapter 45). In the United States, about 10% of allografts are from relatives sharing one HLA haplotype and mismatched for one or more antigens on the unshared haplotype. Results with more than one antigen disparity on the unshared haplotype were disappointing for a long time and there was little increase in the number of these transplants in the 1990s and early 2000s. Some studies suggest that the approach may be successful if T-cell-depleted grafts containing high doses of CD34 cells are administered and if donors are selected to maximize NK cell alloreactivity [51,52]. Another more recent approach involves use of unmanipulated cells with administration of high-dose cyclophosphamide 48–36 hours post-infusion to eliminate the most alloreactive cells [53,54]. The first approach is used more frequently in Europe and the second more frequently in the United States.

If alternative-donor HCTs, whether from unrelated volunteers, unrelated cord blood, or HLA-mismatched relatives, were to be applied in all or most indications currently considered appropriate for HLA-identical sibling transplantation, there would be about 13,000–16,000 allogeneic transplants yearly in the United States. This is far more than the estimated 6000–8000 now being done. It remains to be seen whether increasing awareness of the availability of unrelated donor marrow transplantation or the use of UCB or haplo identical transplants will increase these numbers. There are data to suggest that socio-economic and other, non-HLA issuesalso pose significant barriers to transplantation in suitable candidates [55,56].

Transplantation regimens and supportive care

Historically, with the exception of some transplantations for immune deficiencies, infusion of hematopoietic cells was preceded by intensive immunosuppressive and/or cytotoxic therapy. This treatment is aimed at eliminating malignant cells and, in the case of allografts, host immune cells that mediate rejection. In the 1970s and 1980s, the vast majority of HCTs for malignant disease (primarily leukemia) used a combination of high-dose cyclophosphamide and total body irradiation (TBI), with or without other drugs, for pretransplant conditioning. According to data reported to the CIBMTR, there has been a trend away from the high-dose radiation regimens used in the 1980s and early 1990s. About 35% of all allogeneic transplants for leukemia (60% of those in patients older than 60 years) are now done using reduced-intensity regimens. About 30% of allogeneic transplants for leukemia are done with high-dose busulfan, usually with cyclophosphamide with or without other drugs, and another 30% with high-dose TBI with cyclophosphamide or other high-dose chemotherapy. The remainder are carried out with a variety of high-dose chemotherapy regimens. High-dose therapy regimens for autologous transplants vary according to the underlying disease, but only a minority include TBI.

Another important change in allogeneic HCT strategy has occurred in the approach to post-transplant immune suppression. In the 1970s and early 1980s, methotrexate (MTX) was used. In the middle 1980s, the calcineurin inhibitor cyclosporine (CSP) was substituted for MTX in many centers. In the middle 1980s, a regimen combining MTX and CSP was introduced, which proved to be superior to either MTX or CSP alone for preventing GVHD [57,58]. Tacrolimus is now the more commonly used calcineurin inhibitor.The most common post-transplant immune suppressive regimen in 2011 was tacrolimus plus MTX, used for about 40% of allotransplants. Another 25% of allograft recipients received tacrolimus with mycophenolate mofetil or other drugs. About 35% received cyclosporine with MTX or other drugs. The risk of grade III–IV acute GVHD after HLA-identical sibling HCT decreased from more than 20% to less than 15% between the 1970s and the 1990s, and is less frequently fatal, accounting in part for the substantial decrease in early post-transplant mortality over the past three decades (CIBMTR Statistical Center, unpublished data) (Figure 2.4).

Also contributing to this decrease was better prevention of cytomegalovirus (CMV) disease through use of CMV-negative or filtered blood products for CMV-negative patients and prophylaxis, or early treatment, with ganciclovir in CMV-positive patients or CMV-negative patients receiving grafts from CMV-positive donors. This reduced the incidence of CMV pneumonia, a lethal complication of allogeneic transplantation, from about 10% to <2% (Figure 2.4). Noninfectious pneumonitis (idiopathic pneumonia syndrome) also decreased, possibly from decreased use of MTX and unfractionated radiation but also from better methods of identifying previously undetected micro-organisms. Use of peripheral blood hematopoietic cell grafts and growth factors has hastened hematopoietic recovery and decreased hospital stays, particularly after autologous grafts. Some of the latter are now carried out, at least partly, in the outpatient setting.

The net effect of these and other changes has been a decrease in transplant-related mortality in the first year after HLA-identical sibling HCT, according to CIBMTR data, from about 50% in 1970–1979 to about 15% in 2000–2009 (Figure 2.4). Transplant-related mortality after autologous transplants is even lower: about 5% after autologous transplants for leukemia, and <5% after autologous transplants for lymphoma and myeloma (CIBMTR Statistical Center, unpublished data). Causes of death after allogeneic and autologous transplantation are shown in Figure 2.5. Transplant-related toxicities predominate after allogeneic HCT; recurrent malignancy predominates after autologous HCT.

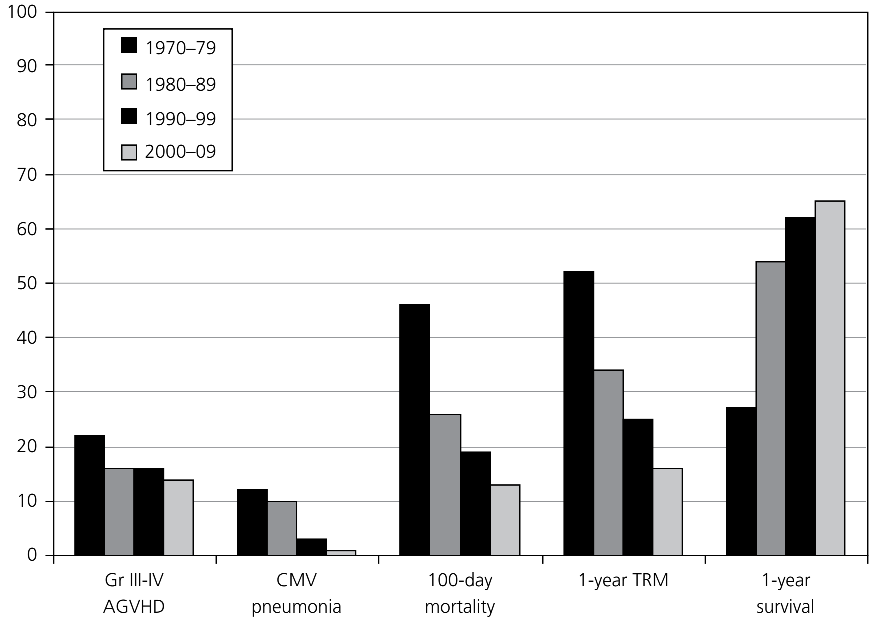

Figure 2.4 Incidence of grade III–IV acute graft-versus-host disease (AGVHD), cytomegalovirus (CMV) pneumonia, and 100-day overall mortality, 1-year transplant-related mortality (TRM), and 1-year survival after human leukocyte antigen-identical sibling hematopoietic cell transplantation (HCT) for leukemia among patients reported to the Center for International Blood and Marrow Transplant Research by year of HCT. Data from the CIBMTR Statistical Center.

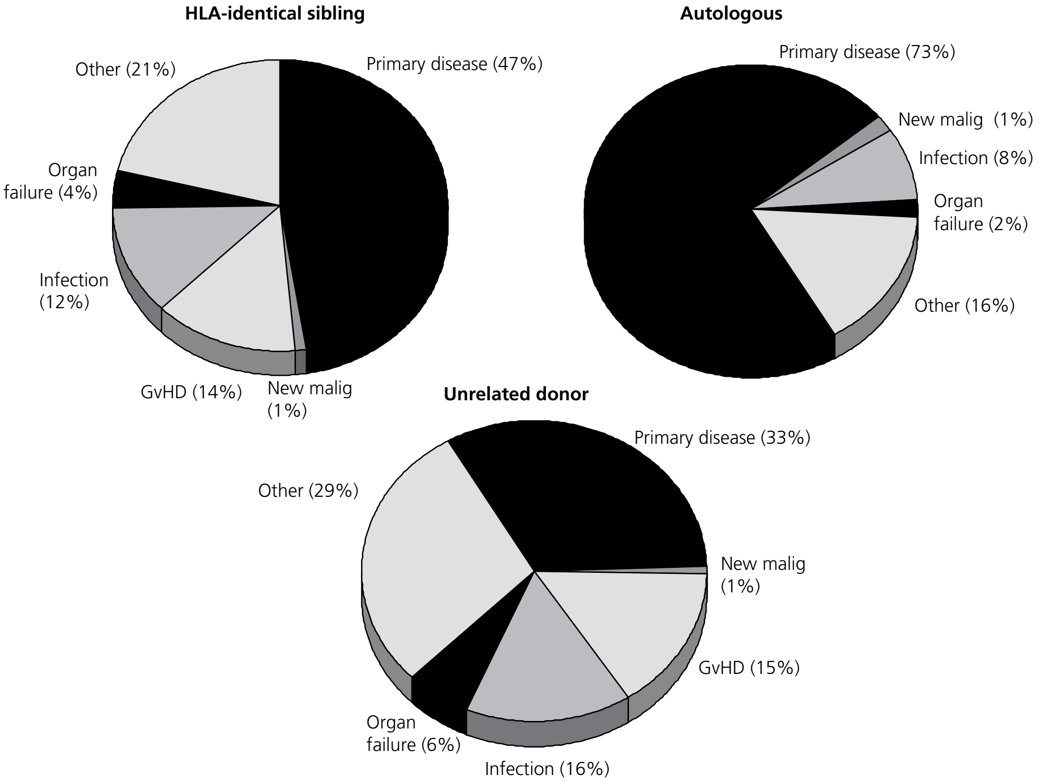

Figure 2.5 Causes of death after HLA-identical sibling, unrelated donor, and autologous hematopoietic stem cell transplantations done in 2008–2009. GVHD, graft-versus-host disease; IPn, interstitial pneumonitis.

Long-term survivors

The increasing use of HCT and better outcome of recipients means increasing numbers of long-term transplant survivors. There are now about 250,000 persons surviving 5 years or more after transplantation, and that number will grow rapidly. Most 5-year survivors are well, off all immune suppression, and leading normal lives. However, recent data suggest that the mortality rate for transplant recipients remains elevated compared to that of an age- and sex-matched general population for many years [59,60].

Transplant recipients remain at risk for late complications long after HCT (see Chapter 104) [59–61]. These include late infections, cataracts, abnormalities of growth and development, thyroid disorders, chronic lung disease, cardiovascular disease,and avascular necrosis. All of these are more frequent in patients with chronic GVHD. There is also an increased incidence of leukemias, myelodysplasias, and solid tumors in transplant recipients compared with the general population (see Chapter 105). Second cancers and other complications may not all be due to HCT per se but to the chemotherapy and/or radiation preceding the HCT. Regardless, lifelong surveillance is necessary, as is increased awareness of late complications among the many non-transplant physicians who will care for these patients. The CIBMTR and the European Group for Blood and Marrow Transplantation (EBMT) recently published guidelines for following transplant survivors [61].

Addressing barriers to use of HCT

In the first 2–3 decades of transplantation, availability of a suitable graft was a major barrier to use of HCT, particularly allogeneic HCT. Use of peripheral blood grafts for autologous transplantation, the dramatically increased availability of unrelated volunteer donors and cord blood units and improved outcomes of alternative donor transplantations now make this barrier surmountable for most patients. Yet, only about half of patients who might benefit from HCT undergo the procedure [55]. Socio-economic barriers are considerable. African Americans are significantly less likely to receive autologous, related donor or unrelated donor HCT than Caucasian patients with similar clinical characteristics [56].Lack of insurance, inadequate insurance and high out-of-pocket costs pose significant barriers to patients in the United States(reviewed in [62]). Healthcare infrastructure may also pose barriers. A recent study of allogeneic HCT activity and transplant center capacity from 2005 to 2009 in the United States showed that the number of HCTs increased 30% but HCT bed capacity increased only 17% [63]. A recent NMDP initiative to assess healthcare system capacity resulted in a series of recommendations to address barriers to transplantation, including promoting public policies that ensure adequate financial coverage for all aspects of the transplantation process [64].

Assessing and improving results of HCT

The field of transplantation has been well served by international collaboration to assess outcomes through international outcomes registries such as the CIBMTR (www.cibmtr.org) and the EBMT (www.ebmt.org). Hundreds of transplant centers have contributed clinical data on hundreds of thousands of patients, allowing observational studies to be carried out addressing many important issues in HCT (see Chapter 28). The past 10 years have seen an increasing number of multi-center prospective clinical trials related to HCT and, importantly, the establishment of networks dedicated to addressing issues in HCT. The EBMT has also established a clinical trials office to facilitate multi-center, multi-national trials. In the United States, the BMT CTN (www.bmtctn.net), a large multi-center network sponsored by the US National Heart Lung and Blood Institute and the National Cancer Institute, has accrued more than 5000 patients to trials since 2003 [65]. These initiatives have significantly increased the infrastructure available to translate our rapidly advancing knowledge in cell biology, immunology, and genetics into treatment strategies that will improve outcomes for our patients.

Introduction

In 1998, Thomson et al. described the first derivation of human embryonic stem cells (hESCs) from the inner cell mass of human blastocysts [1]. hESCs are characterized by their unique self-renewal and pluripotent capacity: they can proliferate almost indefinitely in vitro and have the capacity to differentiate into every cell type of the body. This landmark finding generated great expectations: the possibility of limitless supplies of engraftable tissues of all types, including hematopoietic tissues. Moreover, these cells represent a powerful tool to study embryonic development and lineage specification. They can also provide an unlimited resource of specific cell types for drug screening and toxicity testing.

Stem cells are divided into three categories based on their differentiation potential: totipotent, pluripotent, and multipotent (Table 3.1). Fertilized eggs and each cell of the embryo up to the four-cell stage are totipotent. In a suitable environment, they can form an entire organism including all embryonic, extra-embryonic and adult cell types. In contrast, pluripotent cells are not able to independently form a placenta, or to organize the formation of a proper primitive streak. ESCs are pluripotent cells. They can self-renew and differentiate into any cell type of the body. Somatic stem cells that are found in the tissues of adult body or in the cord blood are multipotent. They have a restricted differentiation potential.

Pluripotent cells are transiently present during embryonic development, from the late morula-stage embryo to the primitive ectoderm of the preimplantation blastocyst. True pluripotent cells are generally not found in adult organisms though some reports indicate that they may be derived from testis. While ESCs are considered the counterpart of the pluripotent cells from the embryo, it has been argued that ESCs are culture “artifacts” that do not have an equivalent in the body. Of note, some differences between pluripotent cells in vivo and those cultured have been shown, including gene expression, proliferation rate, cytokine dependence, fidelity of imprinting, and epigenetic changes [2].

In 2006,Yamanaka’s group in Japan demonstrated that somatic cells could be reprogrammed into pluripotent cells that resembled embryonic stem cells [3]. The authors introduced four genes (*Oct4*, *Sox2*, *KLF4* and *c-Myc*) into embryonic or adult fibroblasts and selected the cells that reactivated ESC-specific markers. These cells, called iPS for “induced pluripotent stem,” could self-renew and differentiate into all three germ layers. Their pluripotency was confirmed by the generation of chimeric mice and germline transmission after blastocyst injection [4,5]. Furthermore, the therapeutic potential of these iPS cells was demonstrated in a humanized mouse model for sickle cell anemia [6]. In this report, mutant donor fibroblasts were reprogrammed into iPS and the genetic defect was repaired by homologous recombination. Then the repaired iPS cells were differentiated into hematopoietic progenitors and these cells were transplanted into the donor mice (Figure 3.1). All hematologic and systemic parameters of sickle cell anemia significantly improved after transplantation, providing proof of principle for using iPS in therapeutic settings.

In 2007, two separate teams demonstrated the reprogramming of human fibroblasts using two slightly different sets of four genes [7,8]. This remarkable finding opens the door to generate patient- and disease-specific pluripotent cells (Figure 3.2). In the past 8 years, a large number of publications reported the derivation of iPS lines from different human cell types: fibroblasts [9], adipocytes [10], $CD34^+$ cells [11], endothelial cells [12], or keratinocytes [13], and the usage of several different technologies to introduce the four transcription factors. Although most of the “early” iPS lines were generated using an integrative retroviral or lentiviral system, the most recent lines have been derived using non-integrative systems such as the Sendai virus [14], episomal vectors [15,16], RNA transfection [17], and protein transduction [18]. These iPS lines are completely transgene-free and therefore represent a safer source of cells for transplantation. Thus, the reprogramming of adult somatic cells to ESC-like cells by overexpression of the four “Yamanaka” factors is a very attractive approach to generate pluripotent cells with the same genomic material as the donor. Therefore, these cells could

provide a unique source of unlimited histo-compatible cells for transplantation.

Several groups have demonstrated the capacity of hESCs and iPS cells to differentiate into blood cells [19–23]. Pluripotent stem cells (PSCs) could offer a new source of hematopoietic cells for transplantation. Since these cells would be genetically identical to the person from whom they were derived, they would be particularly appealing as cell therapy. However, the process of blood differentiation from PSCs remains inefficient, the risk of teratoma formation from residual undifferentiated PSCs cannot be dismissed and there is evidence that reprogrammed cells are genetically unstable. Therefore, a long list of issues remains: (1) how can we efficiently derive HSCs or mature blood cells from PSCs?; (2) how can we isolate HSCs or mature blood cells from the heterogenous population of differentiated hPSCs?; (3) are HSCs derived from PSCs capable of hematopoietic repopulation in vivo?; (4) can we generate a sufficient number of mature blood cells for transplantation?; and (5) can we generate immunologically compatible cells?

In this chapter, we present the progress that has been made and the obstacles along the path to the practical use of hPSC-derived HSCs or mature blood cells in clinical transplantation.

Table 3.1 Sources of stem cells and their differentiation potential

	Potential	Sources	Examples
Totipotent cells	All embryonic, extra-embryonic, and adult cells	Early embryo before the four-cell stage	Zygote Each cell from the two- or four-cell stage embryo
Pluripotent cells	All embryonic and adult cells Some extra-embryonic	Early embryo: morula and blastocyst stage Epiblast	Embryonic stem cells Induced pluripotent stem cells
Multipotent cells	Restricted to specific lineages	Umbilical cord Fetus Adult body	Hematopoietic stem cells Mesenchymal stem cells Neuronal stem cells Skin stem cells

Generation of HSCs from ESCs

What have we learned from murine ESCs?

Mouse ESCs (mESCs) possess a robust capacity for hematopoietic specification in vitro. Factors involved in the steps of differentiation from ESC to HSC have been described (Figure 3.3). Two main procedures have been used to differentiate ESCs into blood: embryoid body formation and co-culture with stromal cell lines. Embryoid body formation is routinely used to induce the differentiation of ESCs. Embryoid bodies (EB) can be generated by culturing ESCs in

hanging drops for several days, by culturing the cells in 1% methylcellulose or by plating ESCs in low-attachment dishes, allowing the cells to form aggregates. In the absence of factors that maintain pluripotency, these cells will spontaneously differentiate into all three germ layers.

Gordon Keller first showed that the sequence of events occurring in vitro, from primitive ectoderm to mesoderm to hematopoietic cells, parallels the different steps of the onset of hematopoiesis in vivo by observing the expression of several specific markers [24]. The emergence of hematopoietic progenitors can be detected by the colony-forming unit (CFU) assay. During mESC differentiation, CFU numbers increased from day 3 to day 6, reaching 1% of the total population of EB cells at day 6. At this stage, the majority of precursors was primitive erythroid cells – small nucleated cells expressing embryonic globin. At day 10, the population of primitive erythroid cells decreased, while the populations of macrophages (CFU-M), adult erythroid cells (CFU-E), neutrophils/macrophages (CFU-GM), and mixed precursors (CFU-GEMM) increased. Mast cells and lymphoid lineages were detected at a later stage (day 12–14), but to a lesser extent, suggesting that this in vitro differentiation system is not optimal for the generation of lymphoid lineages.

Hematopoietic development occurred even in the absence of supplemental hematopoietic growth factors. In order to provide a supportive microenvironment, ESC differentiation was often performed directly on stromal cells such as OP9, a stromal cell line derived from newborn op/op mouse calvaria (that does not produce macrophage colony-stimulating factor (M-CSF)), S17 and MS-5 mouse bone marrow stromal cell lines, or AM20–1B4, a stromal cell line derived from the aorta–gonad–mesonephros (AGM) region. Both protocols, EB formation and culture on stromal cell lines, permitted the derivation of primitive and definitive hematopoietic cells with a large predominance of primitive blood cells.

Derivation of HSCs from hPSCs

Several laboratories have derived hematopoietic precursors from hESCs or iPSCs using the two approaches mentioned earlier: embryoid body formation (Figure 3.4) and co-culture with stromal cells.

The first evidence for blood cell derivation from hESCs was described by Kaufman et al. [19]. They co-cultured undifferentiated hESCs on irradiated S17 or C166 (a yolk sac endothelial cell line) for 17 days and showed the emergence of a small population (1–2%) of $CD34^+CD38^-$ cells, consistent with the phenotype of early hematopoietic precursors. This co-culture gave rise to CFUs with a peak at day 17–18 and colonies from multiple hematopoietic lineages. Other groups have co-cultured hESCs on the stromal cell line OP9, showing a faster and greater efficiency for the derivation of $CD34^+$ cells reaching up to 20% after 7 days. Subsequent co-culture of isolated $CD34^+$cells on the MS-5 stromal cell line induced the production of macrophages, mature granulocytes, natural killer (NK) cells, and B lymphocytes [20–22]. The same approach was used to test blood differentiation from several iPS lines and gave very similar results, albeit with greater disparities between lines [25]. Additionally, stromal cells derived from the mouse AGM region or fetal liver, were shown to enhance hematopoietic differentiation from hESC cell lines [26] and favor the derivation of HSCs with long-term repopulation activity.

Despite the relative effectiveness of this co-culture system, reproducibility may be a problem since stromal cells are very sensitive to culture conditions (including density, serum lot, and passage number). Stromal-free approaches, typically using an embryoid body system, have also been explored to test the potential of hESCs and hiPSCs [27] to differentiate into hematopoietic cells. The influence of bone marrow protein-4 (BMP-4) and cytokines on the hematopoietic differentiation within EBs has been assessed and the successful generation of $CD45^+$cells has been shown when combinations of cytokines (stem cell factor (SCF), FMS-like tyrosine kinase-3 ligand [Flt3L], interleukin-3, interleukin-6, granulocyte CSF, and BMP-4) were used [23]. Later, vascular endothelial growth factor-A_{165} (VEGF-A_{165}) was shown to enhance the selective induction of erythropoietic development [28]. These results indicate that hematopoietic commitment can be induced by exogenous factors, an important step to improve the derivation of blood cells from hPSCs. In an effort to eliminate high variability in the differentiation systems, a blood differentiation protocol in serum-free medium was developed [29]. Moreover, Elefanty's group improved the efficiency and reproducibility of the experiment by controlling the size of the EBs [30]. These systems are all highly empirical and remain fairly primitive. It is anticipated that better understanding of the molecular events involved may permit a more targeted and robust system to generate functional HSCs.

Derivation of hemangioblasts from hESCs

It is established in the murine system that both hematopoietic and endothelial cells develop from a common transient precursor, the hemangioblast. Initial evidence came from an in vitro mouse ESC differentiation system [31]. Within 3 days of differentiation into EBs, a population of cells with hemangioblastic properties could be detected. When cultured in methylcellulose, hemangioblasts could form blast colonies that had both endothelial and hematopoietic potential. The blast-colony-forming cells expressed genes, such as *Scl*, *Flk1*, and *CD34*, which are common to both hematopoietic and endothelial cells. These blast colonies contained endothelial progenitors as well as primitive and definitive hematopoietic cells. Importantly, clonal analysis demonstrated that a single cell could result in the development of both blood vessel and blood cells. Since this seminal report, the existence of the hemangioblast has been demonstrated in both embryonic and adult murine tissues [32,33].

Demonstration of a comparable human cell has been more complicated. However, a number of reports now support that hemangioblasts can be generated from human pluripotent stem cells [34–36]. In particular, a method in which human ESCs were first differentiated into EBs (by BMP-4, VEGF, SCF, thrombopoietin, and Flt3L) and, after 3.5 days, dissociated and plated in semisolid medium, has been shown to improve several aspects of hemangioblast generation. Specifically, the system has several advantages: (1) it is serum free (and therefore more reproducible than protocols using serum due to variations between lots); (2) it allows the generation of a high number of blast cells (20–50 million blast cells can be generated in a week from 1.2 million undifferentiated hESCs); (3) these blast cells can be cryopreserved; and (4) they can differentiate into endothelial cell and multiple hematopoietic lineages. This protocol represents a significant advance toward the derivation of a high number of hematopoietic cells from hESCs for clinical use. Interestingly, when applied to hiPS lines, this protocol showed a markedly decreased efficiency of hemangioblast production, mostly due to senescence and apoptosis [37]. At the same time, another report demonstrated the limited neuronal differentiation potential of iPS lines compared to hESC lines, regardless of the reprogramming method used. These results challenged the idea that iPS cells could provide an unlimited source of cells for transplantation [38]. Although these reports are of concern, they are limited and contrast with many studies that have shown similar yield and proliferation for derivatives of hESC and hiPSC.

Derivation of blood-specific lineages from hPSCs

The development of culture conditions that induce specific lineages is of great interest for both studying the events resulting in lineage differentiation and generating cells that might be useful in adoptive transfer for therapy. Erythroid cells can be used in transfusion to treat patients with anemia or patients who had massive blood loss due to trauma. Platelet transfusions are often prescribed for patients undergoing chemotherapy, bone marrow transplant, or other organ transplant. It is also given to patients with life-threatening thrombocytopenia. Many pre-clinical studies have shown the potential for using T cells, dendritic cells, or NK cells in immunotherapies to treat cancer. Human pluripotent stem cells could provide a renewable cell source for these cell therapies. With the rapid progress in the generation of safer iPS lines, it is now conceivable to obtain patient-specific mature blood cells suited for transplantation.

T cells

In 2006, a system enabling the derivation of T cells from hESCs was established [39]. This two-step protocol, combining preliminary differentiation on OP9 followed by secondary culture into human thymic tissue in immunodeficient mice, showed that hESCs could yield mature T cells when placed in a supportive environment. Resultant thymocytes were able to respond to T-cell receptor-mediated signals. This protocol was later improved by replacing the OP9 co-culture with EB formation in the first step of the differentiation [40]. Although these findings could have therapeutic implications, for instance for patients with X-linked severe combined immunodeficiency disease or infected with human immunodeficiency virus, the in vivo secondary culture is cumbersome and the number of T cells produced is limited. Another system was developed to efficiently induce T-cell differentiation from mouse ESCs [41], where, after an initial differentiation on OP9, the cells were transferred to OP9 expressing the Notch receptor ligand Delta-like 1 (OP9-DL1). The co-culture on OP9-DL1 was also shown to enhance T-cell differentiation of human hematopoietic progenitor cells from bone marrow or umbilical cord blood (42,43). This in vitro approach has since been tested on hESCs with limited success. Two groups were unable to derive T cells from several human ESC lines [44,45] whereas one report demonstrated successful generation of T cells from one hESC line (H1) using this protocol [46]. After 10–12 days on OP9, the authors noted the formation of endothelium-lined cell clumps, reminiscent of blood island structures, which they called hematopoietic zones (HZs). They contain $CD34^{hi}CD43^{lo}$ cells that can be picked and differentiated further on OP9-DL1 cells. After 4–6 weeks in culture on OP9-DL1, 15–50% of the human cells were $CD3^+$. These cells were shown to be functional and polyclonal T cells.

Although, there is evidence that mature T cells can be derived from human pluripotent stem cells using a completely in vitro culture system, it is clear that more efficient, more robust, and more consistent in vitro protocols need to be developed. Additionally, iPS lines have been generated from T cells by several groups [14,47]. This opens the door for the generation of autologous iPS lines with antigen-specific T-cell receptors (TCRs) that could be used in adoptive T-cell therapy to treat cancer. Although this strategy seems promising, the time, cost, and low efficiency of T-cell differentiation remain major obstacles.

B cells

Differentiating pluripotent stem cells into B lymphocytes has proven to be extremely difficult. In 2005, Vodyanik et al. differentiated hESCs with a two-step protocol and detected a low percentage (around 2%) of $CD19^+CD45^+$ B-cell precursors. The hESCs were initially differentiated on OP9 stroma followed by the isolation of the $CD34^+$ cells by MACS and their culture on MS-5 stroma for 21 days [20]. Using a similar protocol, pre-B cells were generated from human iPS cells [48]. These cells were positive for CD19 and CD10 but negative for CD5 and IgM, consistent with a pre-B phenotype.

NK cells

Currently, a large number of clinical trials are under way to test the safety and efficacy of NK-cell based immunotherapy to treat cancer. Evaluating different sources of NK cells for cell therapy is important to obtain large numbers of cells.

hESCs have been shown to differentiate into mature functional NK cells [23,49,50]. CD34$^+$/CD45$^+$ cells were obtained by differentiating hESCs on the stromal cell line S17 and these cells were further directed to differentiate into NK cells by co-culture on the murine fetal liver AFT024 cell line. A highly enriched homogenous population of NK cells was obtained within 4–5 weeks. These cells displayed a normal phenotypic profile with expression of CD56, killer immunoglobulin-like receptor, and CD94/NKG2, markers of mature NK cells. More importantly, these cells exhibited cytolytic activity against human tumor cells by direct cell-mediated cytotoxicity and antigen-dependent cellular cytotoxicity. The same group reported the generation of NK cells from iPS lines and demonstrated their anti-HIV activity [51]. Thus, these cells are not only a valuable means to study NK development, but could also provide a novel source for cellular immune therapy. However, one major limitation of this protocol is the use of a two co-culture system. The development of new, feeder-free differentiation culture is essential to move toward PSC-NK cell therapy.

Macrophages

Using a related strategy, macrophages were derived from hESCs [52]. After 14–17 days of initial differentiation on the S17 stromal cell line, the hESC-derived CD34$^+$ cells were grown in semisolid methylcellulose medium to obtain myeloid colonies. They were then cultured for an additional 2 weeks in liquid culture with cytokines (granulocyte–macrophage CSF and macrophage colony-stimulating factor). The resulting cells expressed CD14, human leukocyte antigen-DR (HLA-DR), CD4, CCR5, and CXCR4, and exhibited normal functions, as measured by phagocytosis, upregulation of B7.1 and cytokine secretion in response to lipopolysaccharide stimulation. The cells were also able to be genetically modified by lentiviral transduction, suggesting potential opportunities for their use as protein-secreting immune cells. Improved protocols for the derivation of macrophages from hESC and hIPS lines have been described [53,54], offering higher efficiency and a feeder-free system.

Dendritic cells

Dendritic cells (DCs) are potent antigen-presenting cells (APCs) with an ability to elicit primary T-cell responses. They can be used to stimulate the immune response against tumor-associated or viral antigens or, in contrast, to diminish immune response in autoimmune diseases or after transplantation. Immature DCs can be isolated from peripheral blood or derived from bone marrow CD34$^+$cells [55,56]; however, hPSCs could potentially provide an unlimited number of DCs. A three-step approach was used to generate DCs from hESCs [57]. These cells expressed similar markers to HSC-derived DCs, such as CD1a, CD9, CD68, and CD86. Moreover, these cells were functional, as shown by their ability to induce the proliferation of adult and cord blood T cells and their capacity to present antigens through the major histocompatibility complex (MHC) class I pathway. Using the same three-step approach, functional DCs were generated from additional hESC and hiPS lines [53,58]. The iPS-DCs were shown to be functional through their capacity to induce the proliferation of cytomegalovirus specific autologous T cells after being loaded with cytomegalovirus peptide. This three-step protocol was further improved by replacing the OP9 co-culture with a clinically compatible feeder-free system [59,60].

One strong advantage in using pluripotent stem cells as a source of APCs is their potential to be genetically modified. One group reported the derivation of genetically manipulated DCs from hESCs [61]. They used a plasmid to overexpress the human mutated CD74 in hESCs and selected clones with high transgene expression at the pre-DC stage. They further show that these DCs could activate specific T cells without adding peptides. Thus, with the rapid development of genome modification technologies like Zinc-finger, TALEN, and CRISPR, the generation of genetically engineered hPSC DCs could offer a promising tool for antigen-specific immune therapy.

Erythroid cells

PSCs, as self-replenishing units for the production of large numbers of cells, have long been considered as a mode of generating red blood cells ex vivo. One consideration, however, is that the red blood cells produced may represent those of early embryonic development. The primitive erythroid cells found in the yolk sac during human development have a characteristic morphology: they are nucleated and express mostly embryonic globin(ε, ζ, and α). In the fetal liver, macrocytic erythrocytes are enucleated and express fetal globin ($\alpha2\gamma2$), while mature, marrow-derived erythrocytes are characterized by adult globin ($\alpha2\beta2$).

Many reports have shown the generation of erythrocytes from hESCs and hiPSCs. A review from Chang, et al. summarizes the work published in the past 10 years [62]. In brief, red blood cells could be produced from any PSC, but the efficiency and maturity of the cells varied depending on the protocol used and the lines. The highest efficiency (200,000 erythroid cells per hESC) was obtained after co-culture on OP9 and MS5 [63]. However, only a small percentage of these erythroid cells were enucleated and they only expressed embryonic globin. In contrast, other groups were able to derive erythroids with a higher percentage of enucleated cells, up to 66% using the EB method [64,65], but the efficiency was lower and the erythroid cells remained of embryonic origin as shown by the lack of β globin expression. In conclusion, regardless of the differentiation method, it remains a challenge to produce fully mature erythroid cells from pluripotent stem cells. Interestingly, this is a problem for any cell type generated from PSCs and emphasizes the importance of the microenvironment for the full maturation of PSC-derived cells. One way to overcome this problem is to induce terminal differentiation in vivo. A recent paper from Kobari et al. showed that erythroblasts could achieve full maturation (nucleus expulsion and expression of adult Hb) a few days after injection into NOD/SCID mice [66]. Although, this is a proof of principle that mature erythroid cells can be obtained from PSCs, this method is not suitable for the generation of red blood cells for clinical use.

Megakaryocytes/platelets

Developments in differentiation protocols and the fact that platelets are anucleate (thereby eliminating the concern about genetic stability of pluripotent cells) have rapidly made this an area where pluripotent cell products are moving to the clinic. In 2008, Takayama et al. established a protocol to generate functional platelets from human embryonic stem cells. Human ESCs were first differentiated by co-culturing on irradiated C3H10T1/2 or OP9 cells in the presence of VEGF. After 2 weeks in this condition, hESCs formed sac-like structures containing round, hematopoietic-like cells. In the presence of TPO, SCF and heparin, these cells further differentiated into megakaryocytes expressing CD41a, CD42a, and CD42b that could release functional platelets [67]. Using a different protocol, Lu et al. were able to generate platelets from hESC with higher efficiency and showed their functionality in vivo [68]. Because platelets are enucleated and irradiation can be used to eliminate possible contaminating nucleated cells, they are the most promising pluripotent stem cell-blood derivative candidate for clinical trials. One of the major obstacles to the use of PSCs derived platelets for transplantation is the number of platelets needed. The standard dose is between 3×10^{11} to 6×10^{11} platelets. However, one clinical trial using hiPSC-derived platelets is in preparation in Japan, led by Dr. Koji Eto with phase I/II scheduled in few years.

Isolation and/or expansion of hPSC-derived HSCs

It is clear that hPSCs can be differentiated into blood cells at various stages of commitment. Although the protocols cited earlier allowed for blood cell generation, the cells were not homogeneous, and the isolation of the cells of interest would be necessary before transplantation. Isolation would address the major concern that some undifferentiated PSCs could remain in the population of cells being transplanted. Since undifferentiated PSCs have the potential to form teratomas (benign tumor-containing cells from the three germ layers) when injected into SCID mice, it is crucial to eliminate any residual undifferentiated PSCs prior to transplantation. A negative selection could be performed using well-known surface markers specifically expressed in hPSCs, such as TRA-1-60, stage-specific embryonic antigen-3 (SSEA-3) or SSEA-4. Alternatively, it has been proposed to generate a human PSC cell line that expresses the herpes simplex virus thymidine kinase gene [69]. Since this gene confers sensitivity to the drug ganciclovir, specific elimination of transplanted hESC-derived cells could be accomplished by use of ganciclovir in the case of tumor development.

Another issue is the presence of cells from other lineages in the heterogeneous population of differentiated cells. Thus, an attractive approach is to positively isolate HSCs or specific blood lineages before transplantation. A limitation is the lack of defined surface markers for the prospective isolation of long-term HSCs. Mouse long-term repopulating HSCs are well characterized, and a panel of surface markers is commonly used to isolate these cells, such as Lin^-, Kit^+, Sca^+, and $\mathrm{Thy1}^{\mathrm{lo}}$ [70]. In 2005, a family of cell surface receptors, the signaling lymphocyte activation molecule family (SLAM), that distinguished long-term HSCs (LT-HSCs) from multipotent progenitors (MPPs), was identified in mice [71]. While CD150 was present exclusively at the surface of LT-HSCs, CD48 was specifically expressed in MPPs. The combination of these two SLAM markers (CD150/CD48) was proven to be very efficient for the isolation of LT-HSCs. Both LT-HSCs and MPPs can give rise to all blood lineages, but only LT-HSCs can maintain lifelong production of blood cells. Thus, the development of this simple and direct method to isolate LT-HSCs was a major step forward to improve transplantation efficiency. However, the expression pattern of CD150 and CD48 is different in humans [72] and their utility to isolate non-human primate LT-HSC has been questioned [73]. Other methods, using CD49f have been shown to be more promising [74].

This marker, like many used to isolate cells, has not been validated in cells derived from pluripotent cells. Whether markers identified on cells derived from the intact organism can be used to isolate the appropriate cell derived from cultured pluripotent cells is not clear. For example, several markers known to be expressed on hematopoietic progenitors, such as CD90, CD133, and CD117, are also expressed in undifferentiated hESCs, limiting the use of these markers for HSC isolation. It is therefore not known if the HSC-enriched $\mathrm{CD34}^+/\mathrm{CD90}^+/\mathrm{CD38}^-$pattern applies to cells derived from human ESCs [75].

Another hurdle for the generation of HSCs from PSCs is the lack of culture conditions allowing the expansion of these cells. During hematopoietic differentiation in vitro, the number of cells with hematopoietic activity (based on the colony-forming cell (CFC) assay) reaches a peak, usually around 2–3 weeks into the differentiation but then rapidly decreases as the cells further differentiate. Additionally, the timing of the peak is different for each line and each protocol used. Unless new culture systems are developed to expand HSCs in vitro, it will be technically challenging to isolate a sufficient number of PSC-derived HSCs for transplantation.

Several strategies have been proposed to enhance HSC ex vivo expansion and a few reports showed improvement in HSC culture systems in the past few years. For instance, using a chemical screen, Boitano and colleagues identified a purine derivative called SR1 that supported a 50-fold increase in cord blood $\mathrm{CD34}^+$ cells [76]. Recently, Zandstra's group reported an 11-fold increase of HSC by inhibiting feedback signaling from differentiated blood cells [77]. Another approach would be to mimic the bone marrow niche using a 3D culture system. A German group has done preliminary work comparing the ability of different 3D scaffolds to support CB $\mathrm{CD34}^+$ expansion [78]. The development of a culture system to sustain HSC growth is currently an active area of investigation.

Are PSC-derived hematopoietic progenitors capable of engraftment and hematopoietic repopulation?

Transplantation of HSCs derived from mPSCs

Although the derivation of hematopoietic progenitor cells from mPSCs has been well documented in the last 25 years, only a few groups have reported a robust long-term repopulation from HSCs derived from mPSCs. In the first reports, the authors overexpressed the transcriptional regulators Hoxb4 and Cdx4 [79,80] in HSCs to increase their engraftment into lethally irradiated mice. In brief, Hoxb4 expression was induced in embryoid bodies at day 4 by addition of tetracycline, followed by dissociation at day 6 and replating on OP9. Only the primitive hematopoietic cells expressing Hoxb4 or the combination Hoxb4/Cdx4 were able to expand in this culture condition. After an additional 2 weeks of co-culture, all of the cells were transplanted into irradiated mice. Engraftment and multilineage repopulation was demonstrated, albeit with low lymphoid potential. Later, similar results were obtained with the overexpression of a LIM-homeobox transcription factor: Lhx2 [81]. This system was more favorable to B-cell differentiation but inhibitory for T-cell differentiation. Although these studies demonstrated the potential for HSCs derived from PSCs to be fully functional, this overexpression system would not be safe for therapeutic applications due to the risk of malignant transformation. Thus, the generation of functional and engraftable HSCs from PSCs remains extremely challenging.

The lack of engraftment of PSC-derived HSCs is thought to be due to the primitive nature of the cells generated. In mammals, hematopoietic development follows a complex process with two successive waves of primitive and definitive hematopoiesis occurring in distinct anatomical sites [82]. Primitive hematopoiesis arises in the blood islands of the yolk sac by day 18 of gestation in humans. It is transient and allows for the production of nucleated erythroblasts, as well as macrophages and megakaryocytes. These primitive red blood cells are critical for the survival of the early embryo, which develops in a highly hypoxic environment. The second wave of hematopoiesis is located in the AGM region in the embryo proper. It is thought that definitive HSCs migrate from the AGM to the fetal liver, where they expand extensively before reaching their final niche in the bone marrow during the second trimester. These definitive HSCs are mostly quiescent but can give rise to all blood cell lineages. In the 1970s, it was thought that yolk sac HSCs colonized the fetal liver, and later the adult bone marrow, giving rise to definitive HSCs. Studies in the 1990s, however, demonstrated that the first definitive HSCs originated from the AGM, independent of the yolk sac blood cells [83,84].

For a decade, this theory of two independent waves of hematopoietic onset, one from the yolk sac that supplies the embryo and one from the AGM that provides definitive adult HSCs, was accepted by many scientists in the field. However, this theory was then challenged by an in vivo cell-tracing approach to follow the fate of yolk sac hematopoietic cells during mouse development [85]. Using time–genetic labeling of yolk sac hematopoietic cells, it was demonstrated that yolk sac-derived cells can indeed migrate into sites of definitive hematopoiesis and contribute to blood cell production in adults. Work from another group further demonstrated that definitive HSCs could be derived from yolk sac if the cells were co-cultured with an AGM stromal cell line [86]. This observation implied that the AGM provided the specific microenvironment allowing the maturation of the yolk sac primitive HSCs into mature definitive HSCs. It may therefore be possible to instruct primitive cells derived from PSCs to provide engraftable HSCs.

Transplantation of HSCs derived from human PSCs

The repopulating potential of hPSC-derived HSCs has been reported to be quite poor [87]. However, when hESC-derived HSCs were injected directly into the marrow cavity, rather than the bloodstream, of irradiated immunodeficient mice, human blood cells were found at the site. There was even evidence that similar cells could be secondarily transplanted [88]. However, in all cases the level of engraftment was very low (<1%) and inferior to that of somatic sources of HSCs. The engraftment was slightly increased when the hESC were differentiated in a co-culture system using primary cells or cell lines derived from the AGM or fetal liver [89]. In this study, human blood cells were detected in the injected and non-injected femur, as well as the peripheral blood of all surviving mice. These hESC-derived HSCs were also capable of secondary transplantation. However, the level of blood reconstitution in the peripheral blood remained very low. Overexpression of Hoxb4 in HSCs derived from hPSCs was also tested, but unlike in the mouse system, the engraftment potential was not increased [90]. The enforced expression of Cdx4 or Lhx2 has not been tried yet. In conclusion, little progress has been made over the past decade to enhance the capacity of HSC-derived PSCs to engraft.

Can we generate immunologically compatible HSCs?

Another major concern for the use of hPSC-derived blood cells in transplantation settings is their potential for being rejected by the recipient in the same manner that any conventional transplanted organ is rejected. One approach to circumvent this problem is to use traditional immune regimens to prevent PSC derivatives rejection. Pearl et al. demonstrated that a short treatment with a combination of three co-stimulatory receptor blocking agents could enhance engraftment of hESC or hiPSC and, more importantly, their derivatives [91]. However, this procedure may not be adequate for highly immunogenic blood cells.

Several additional strategies have been proposed to limit the likelihood of tissue rejection if hPSC-derived hematopoietic cells ever become available for transplantation: (1) the creation of a global bank of hPSCs; (2) the use of the potential immune privileged status of hPSC derivatives; (3) the generation of tailor-made hPSCs by reprogramming patients' somatic cells (induced pluripotent stem (iPS)); and (4) the direct reprogramming of patients' fibroblasts into blood cells. In the following paragraphs, we review these different approaches.

Creation of a global hPSC bank

Attempts to define the HLA complexity of an hPSC bank needed to cover a reasonable segment of the population have been performed. One study analyzed the blood group and HLA types of 10,000 UK cadaveric organ donors for compatibility with 6577 patients registered on the UK kidney transplant waiting list, and used it as a simulation model for the potential requirement for hESC-derived cell transplantation [92]. This study was based on a six-antigen match. The authors reported that as few as 150 hESC cell lines would provide a full match for a minority (less than 20%) of patients, but a beneficial match (meaning one HLA-A or one HLA-B mismatch only) for 38% of the recipients and an HLA-DR match for 84%. They suggested that only 10 cell lines homozygous for common HLA types would provide a complete match for 38% of the patients and a beneficial match for 67%.

One caveat of this study is the underrepresentation of particular ethnic groups. Another study carried out on the Japanese population showed similar results [93], estimating that a bank of human ESC cell lines derived from 170 randomly selected embryos would provide 80% of patients with, at worst, a single mismatch at one HLA locus. We have to keep in mind that this data was obtained from a relatively homogeneous population. A much larger number of cell lines will be required to offer a good match to ethnic minorities. The ethical aspects associated with the creation of an hPSC bank are complex and have been well articulated elsewhere [94].

Immune privileged?

Several studies have suggested that hESCs and their differentiated derivatives are immune privileged and may circumvent rejection [95,96]. Supporting this claim, hESCs have been shown to express low levels of MHC class I proteins and to lack expression of MHC class II antigens [97]. However, MHC class I expression increased during differentiation and could be rapidly induced by interferon treatment. Since NK cells target low-expressing MHC class I cells through a process called "missing self," the expression of NK receptors on the surface of hESCs was checked [97]. hESCs did not express the NK receptor and thus were not subjected to NK-mediated lysis. This finding suggested that engrafted hESCs could escape the innate immune response.

In another study, the same group further studied the immune response against hESCs and derivatives in vivo [96]. Although teratomas could develop into NOD/SCID mice after 1 month, no tumors were found in NK-cell-deficient, B-cell-deficient, or immune-competent mice, implying that xenorejection of hESCs was T-cell dependent. In order to mimic the clinically relevant transplantation settings, they used a humanized (Trimera) mouse model [98] to evaluate allorejection of hESCs. Both hESCs and their derivatives could escape rejection and form teratomas when injected into the mice reconstituted with human peripheral blood monocytes. In contrast, transplanted human skin fibroblasts and B lymphocytes induced a donor leukocyte response and were completely eliminated.

The alloantigen-specific immune response against hESCs was also examined in vivo [95]. hESCs were injected intramuscularly into immunocompetent mice. Unlike the human MBA-1 control cells (megakaryocytic cell line), hESCs did not induce an inflammatory response in these mice. Moreover, hESCs and their derivatives had a limited ability to induce T-cell-mediated immune responses. In fact, their data suggested a direct inhibitory effect of hESCs on T-cell proliferation in response to allogeneic DCs. These immune-privileged properties of hESCs are reminiscent of the tolerance of maternal lymphocytes for embryonic cells. However, these properties were challenged in another study [99]. The authors demonstrated that hESCs induced a similar response to human fibroblasts on naïve and immunized T cells, both directly and in the presence of syngeneic DCs. More data needs to be collected to confirm and understand the partial immune privilege revealed in these reports. The hESC derivatives used in these studies were the result of random differentiation through teratoma formation. No MHC class II expression was detected in this population of cells, which suggests a poor efficiency for hematopoietic differentiation or the presence of immature blood cells only. Blood cells are particularly immunogenic, so further work needs to be performed on the immune response of this specific lineage.

Pluripotent stem cells tailor-made by reprogramming patients' somatic cells (iPS)

One strategy to avoid graft rejection is to generate cell lines with the genomic material of the patient. In this case, the match would be perfect and the risk of rejection minimal. Several methods have been attempted to generate patient-specific pluripotent stem cells such as somatic cell nuclear transfer, somatic–embryonic cell fusion or the generation of parthenogenetic ESCs. However, these methods were unsuccessful for human cells or had strong limitations.

It is clear now that the method of choice to generate patient-specific pluripotent stem cells is somatic reprogramming. This method was described for the first time by Shinya Yamanaka in 2006, an achievement that earned him the Nobel Prize of Medicine in 2012. This relatively simple protocol allows somatic cells to be reprogrammed by overexpressing four genes (*Oct4*, *Sox2*, *Klf4*, and *c-Myc*). The iPS lines generated through this protocol show great similarity to hESCs: they can expand indefinitely and can be differentiated into any lineage, in theory, offering an unlimited supply of blood cells. With the recent advances in the generation of integration- and transgene-free iPS lines, iPS-derived cells could be an ideal source for hematopoietic cell transplantation.

In principle, the risk of immune rejection in an autologous setting, where the patient's own iPS cells are used as a source of cells for transplantation, should be minimal. However, one report, published in *Nature*, showed an unexpected immune response following iPS cell transplant in genetically matched mice [100]. The team generated iPS lines from mouse skin cells and transplanted them into mice that were genetically identical to the donors. Surprisingly, most of these iPS lines could not form teratomas since they quickly triggered an immune rejection. Although this study serves as a cautionary note for the use of PSCs in clinical settings, additional work must be done to evaluate the immune rejection of iPS derivatives instead of undifferentiated iPS as described in this paper. Moreover, iPS lines generated using different reprogramming technologies should be assessed to find out whether the reprogramming methods could influence the immunogenicity of the resulting iPS lines.

Nevertheless, producing new iPS lines for each patient would be an extremely expensive, time-consuming and complex process. A proposed alternative is to create banks of hiPS lines with HLA genotypes that would match a majority of the potential recipients. Unlike hESC banks, iPS banks could select the donors based on their HLA haplotype and therefore be less random. Four reports described different models to define the number of iPS lines needed to offer a match for some specific populations. Two studies focused on the Japanese population. Okita et al. derived iPS lines from two individuals that could, in theory, match ~20% of the Japanese population [101]. Another group calculated the number of iPS lines appropriate to cover most of the Japanese population. They estimated that a cell bank of 50 iPS lines would offer a matched line to 90.7% of the population [102]. A similar study showed that a bank with 150 iPS lines would be sufficient to match 93% of the UK population [103]. This report used the HLA database established by the Bone Marrow Donors Worldwide (BMDW) to evaluate the feasibility of selecting donors homozygous for each HLA haplotype. Other models were established to evaluate the size of the banks to match potential recipients from different countries. This is summarized in a review from Zimmermann [104]. Overall, the feasibility of such banks has been demonstrated and the derivation of GMP-grade iPS lines has already been accomplished.

Direct reprogramming of patients' fibroblasts into blood cells

An interesting new approach for obtaining blood cells was published in 2010 [105]. It originated from an observation that many colonies with round cells, resembling blood cells, were generated during the reprogramming of human dermal fibroblasts into pluripotent stem cells. These cells were $CD45^+$ and lacked the pluripotent stem cell marker TRA-1-60. Interestingly, the authors showed that most of these $CD45^+$ cells expressed only one of the four "Yamanaka" factors: Oct4. Based on this observation, they tested whether overexpression of Oct4 was sufficient to directly reprogram fibroblasts into blood cells. Using a lentivirus system to introduce Oct4 into fibroblasts, they were able to get 24–38% of $CD45^+$ cells 21 days after transduction. They demonstrated that these cells were multipotent hematopoietic progenitors capable of differentiating into myeloid, erythroid, and megakaryocytic lineages in vitro and in vivo. Unlike the erythroid cells generated from PSCs, the erythroid cells derived with this direct reprogramming system express adult β-globin protein. Although this work has not yet been reproduced by other groups, many reports on direct conversion of fibroblasts into neurons [106], motor neurons [107], cardiomyocytes [108], and endothelial cells [109] have been published within the last few months.

In conclusion, this approach offers a faster and cheaper way to generate hematopoietic cells. Nevertheless, the limited proliferation of the fibroblasts and of the multipotent hematopoietic progenitors is a major restriction to the use of this technology to obtain the large number of cells needed for transplantation.

Conclusion

The ability to use pluripotent cells derived either from embryos (hESCs) or reprogrammed somatic cells (iPSCs) as a source of HSCs for transplantation remains a distant possibility. More experiments need to be done to understand how these cells normally mature to acquire the characteristics of adult HSCs, and how these steps in ontogeny may be controlled and accelerated in laboratory settings. It is worth recalling that approximately 20 years separated the first derivation of mESCs [110,111] and definitive proof of long-term multilineage engraftment of HSCs derived from mESCs [112].

Research on the derivation of definitive engraftable HSCs from human pluripotent stem cells is still in its infancy. In contrast, striking progress has been accomplished in the derivation of mature blood cells. In particular, new protocols were developed to generate mature functional erythrocytes and platelets on a large scale. Since these blood cells are enucleated, their transfusion presents a lower risk for the patient. Therefore, the transplantation of red blood cells and platelets from immunologically compatible PSCs represents the most practical strategy for PSC-derived blood cell-based therapy.

Since the previous edition of *Thomas' Hematopoietic Cell Transplantation*, three clinical trials using derivatives of embryonic stem cells have been allowed to proceed by the U.S. Food and Drug Administration (FDA). The transplantation of hESC-derived oligodendrocytes in spinal cord injury was begun but closed prior to completion due to financial considerations. Two additional clinical trials are still active testing the safety of using hESC-derived retinal epithelial cells in Stargardt macular dystrophy and age-related macular degeneration. Therefore, regulatory guidelines governing pluripotent cell products are being developed and clinical testing has begun. These critical first steps will greatly influence whether and how hematopoietic cells from pluripotent cells will be introduced into medicine.

We cannot know yet whether pluripotent cells will provide a clinically useful source for hematopoietic cell transplants in humans. However, these cells have tremendous potential as both a research tool and a possible therapeutic agent, a potential that can only be defined by further vigorous investigation.

CHAPTER 4

Hematopoietic Stem Cells, Regenerative Medicine, and Leukemogenesis

Irving Weissman
Stanford Institute for Stem Cell Biology and Regenerative Medicine, Ludwig Center for Cancer Stem Cell Research and Medicine at Stanford University, Stanford University School of Medicine, Stanford, CA, USA

Introduction

Stem cells are single cells that are capable of both self-renewal and differentiation [1–3]. In essence, self-renewal means that the cells can divide without undergoing discernible differentiation, and that they possess properties that allow large numbers of self-renewing cell divisions to occur in a regulated fashion over the life span of a host. Hematopoietic stem cells (HSCs) are therefore blood-forming cells that, at the single cell level, can duplicate by self-renewal as well as produce all types of differentiated blood cells [4]. HSCs were the first prospectively isolated stem cells that give rise to organs or tissues [5,6], and their properties stand as a model for other tissue and organ stem cells. Based on their definition, stem cells must make their first appearance at the beginning of organ and adult tissue development, because at this stage there are no residual cell types that were first seen in the embryonic stages that precede fetal development.

Failure of hematopoietic cell transplanters and journals to use appropriate terms to describe the cells that are transplanted

Many investigators misuse the term stem cells when they transfer other populations of cells. In this volume, and hopefully in the journals that serve this field, hematopoietic cell transplantation (HCT) means that the inoculum contains hematopoietic cells. Bone marrow (BM), mobilized peripheral blood (MPB), and umbilical cord blood (UCB) are common sources of cells for HCT. Collections of cells from these sources can be enriched for hematopoietic stem and progenitor cells that express CD34 – that is, $CD34^+$ hematopoietic cells – for use in HCT. Transplantation of candidate HSCs in humans has only occurred rarely [7], and different labs use different markers to isolate these candidates. It would seem logical for investigators to specify the phenotypic markers expressed on or absent from the claimed HSCs – for example, $CD34^+38^{lo}CD90^+Lin^-$ HSCs, or $ALDH^+$ HSCs, or dye exclusion cells in the side population, called SP cells, or the more restrictive lowest 10% of these, called SP tip cells. Hematopoietic progenitors may be named either by their function, if enriched or purified, for example, common lymphoid progenitors (CLPs), or by their marker phenotype, for example, $CD34^+38^+CD123^+CD45RA^-Lin^-$ common myeloid progenitors (CMPs).

History of the HSC

Following the demonstration that just lethal doses of whole body irradiation caused death by hematopoietic failure, and that hematopoietic failure could be averted either by shielding hematopoietic organs or by transplantation of unirradiated bone marrow [8–10], the critical study that set the stage for the concept of HSC demonstrated that injected bone marrow reconstituted the hematopoietic system rather than provided radiation repair factors [11–13]. In our view, the seminal set of studies in the HSC field began with the observation by Till and McCulloch that transplantation of limiting numbers of bone marrow cells into lethally irradiated mice gave rise to colonies in the spleen that contained all elements of the myeloerythroid (but not lymphoid) lineages and that the number of colonies was proportional to the number of bone marrow cells injected [14].

Two experiments followed these observations that opened the field to stem cell biology and changed the thinking of the hematology community. First, pre-irradiation of the marrow donor at doses that would allow the survival of some cells that had random chromosome translocations or inversions resulted in the finding that each spleen colony was the product of a clonogenic precursor [2]. Second, at least some of these colonies contained cells that also contained spleen colony-forming cells, as well as cells that could be radioprotective [2,15,16]. Later, it was shown that the daughter cells of some of these spleen colony-forming cells included lymphocytes [17]. These experiments indicated that there probably exist, in the bone marrow, single cells capable of self-renewal and full differentiation to hematopoietic fates. These important experiments were carried out mainly in the 1960s, before the discovery of monoclonal antibodies [18] or the development of high-speed multiparameter fluorescence-activated cell sorters [19]. The eventual isolation of HSCs required not only these innovations, but also the development of in vitro and in vivo assays for the identification and quantification of clonogenic precursors of T-cell [20], B-cell [5], and myeloerythroid lineages [21–24]. Many important enrichments of these precursors were accomplished using cell sorting with monoclonal antibodies and lectins [25]. However, prospective isolation of HSCs was not accomplished until a simultaneous analysis of all lineages was coupled with quantitative reconstitution of hematopoiesis in irradiated mice by limiting numbers of candidate HSCs [5,26–30].

We have isolated both mouse and human HSCs, and their surface phenotypes are shown in Figure 4.1 [29,31,32]. They share the properties of expressing Thy-1 ($Thy1.1^+$ or $CD90^+$) and lacking the expression of a collection of mature blood cell lineage markers (Lin^-) and both express c-kit. In addition, mouse HSCs express the Sca-1 (stem cell

Figure 4.1 Hematopoietic lineage tree, showing cells at successive stages of differentiation with distinctive marker profiles (immunophenotypes) in mouse and human. The hematopoietic stem cell (HSC) has long-term reconstituting, self-renewing capacity; the multipotent progenitors have limited or no self-renewal leading to transient but multilineage reconstitution. CMP, common myeloid progenitor; CLP, common lymphoid progenitor; MEP, megakaryocyte/erythroid progenitor; GMP, granulocyte/macrophage progenitor; MkP, megakaryocyte progenitor; EP, erythroid progenitor; GP, granulocyte progenitor; MacP, macrophage progenitor; Pro-DC, dendritic cell progenitor; Pro-B, B lymphocyte progenitor; Pro-T, T lymphocyte progenitor; Pro-NK, natural killer cell progenitor. (For a color version of this figure, please see the color plate section.)

antigen 1) marker [29,30,33,34] and do not express surface Flk2/Flt3 [31,32], whereas their downstream multipotent progeny express Flk2 [32]. Long-term HSCs (LT-HSCs) were also found to express CD150 (SlamF1). We isolated human HSCs of the phenotype CD34$^+$ [35] Thy-1$^+$Lin$^-$ [36] that were enriched for T, B, and myeloid cell potential in clonogenic assays, and were efficient at restoration of the respective human hematopoietic lineages in SCID-hu mice (i.e., mice with severe combined immunodeficiency bearing renal subcapsular grafts of human fetal liver and thymus) [36]. Human LT-HSCs are, in addition, CD38$^-$ to CD38^{lo} [36–40]. We further characterized LT-HSCs to be contained within the Lin$^-$CD34$^+$CD38$^-$CD90$^+$CD45RA$^-$ fraction of cord blood. Transplantation of as few as 10 of these cells resulted in long-term repopulation in immunocompromised mice. In addition, we found the Lin$^-$CD34$^+$CD38$^-$CD90$^-$CD45RA$^-$ population to contain candidate human multipotent progenitors (MPPs), cells with limited self-renewal potential capable of transient multilineage blood reconstitution [41].

In mice, the Sca-1$^-$, Lin$^+$, c-kit$^-$, Thy-1$^-$, or Thy-1^{hi} subsets do not contain any long-term multilineage hematopoietic potential [34]. In humans, CD34$^-$, Lin$^+$, or Thy-1 cells also do not contain in vitro or in vivo long-term multilineage hematopoietic precursor potential However, some research groups have reported at least some HSCs may be CD34$^-$ [42–44], or Thy1$^-$ [45]; and $\alpha6^+$ [46], as in mice [47]. Only CD34$^+$ or CD34$^+$90$^+$ human HSCs have been successfully transplanted in humans.

In mice, transplantation of limiting dilution or single LT-HSCs results reproducibly in a high frequency of hosts (5–40%) showing long-term multilineage reconstitution, with self-renewal of HSCs [27,28,48–50]. The bone marrow of allogeneic human HCT transplants contains self-renewed HSCs that also engraft upon serial transplantation in SCID-hu mice [36].

Properties of mouse HSCs and other MPPs

Transplantation of downstream short-term (ST)-HSCs or MPPs results in robust but transient multilineage reconstitution after which residual host HSCs recover [28,29,32]. However, no matter how many ST-HSCs or MPPs are transplanted, at no time is there any measurable de-differentiation from the short-term cells into the long-term pool [30].

In the normal steady state, 2–8% of LT-HSCs randomly enter cell cycle each day, whereas higher percentages of ST-HSCs and MPPs are in cell cycle at any time [51–53]. Interestingly, when steady-state bone marrow LT-HSCs are isolated according to their position in the cell cycle, those cells with 2N DNA content efficiently provide radioprotection and long-term multilineage reconstitution, whereas the dividing subsets (>2N DNA content) are less efficient at reconstitution and similarly less efficient at homing directly to the bone marrow [51,52,54]. Within the 2N DNA pool of LT-HSCs, the G_0 cells engraft more readily than those in G_1 [52]. Following transplantation, a much higher fraction of LT-HSCs remain in cell cycle in the radioprotected host, and this period can extend for at least 4–5 months after transplantation [30,50,51,55]. Given the poor transplantability of cycling HSCs, it is conceivable that protocols that test cells for "stemness" by serial transplantation could be confounded by these lingering effects of mobilization and radiation on cell cycle status and reconstitution ability [50,51,55].

Although in the steady state most HSCs are quiescent, and only a small fraction of LT-HSCs is in cell cycle, this ratio can be dramatically altered by a number of circumstances. For example, upon transplantation into irradiated hosts, probably every HSC that lands in a hematopoietic microenvironment undergoes, at least initially, symmetrical self-renewing cell divisions to expand the HSC pool. In addition, the techniques used to mobilize HSCs into the bloodstream usually operate by first causing all HSCs to enter the cell cycle non-randomly [54,56,57]. As shown in Figure 4.2, treatment of a mouse with cyclophosphamide (CY) (which should kill no more than 4–8% of LT-HSCs, but should have a dramatic effect on both multipotent progenitors and oligolineage progenitors (see later) because they are largely in cell cycle) followed by granulocyte colony-stimulating factor (G-CSF), results in every HSC entering cell cycle, leading to a 12- to 15-fold increase in the steady-state number of LT-HSCs [56].

HSCs must go through many self-renewing cell divisions over the life of an animal, raising the question of whether they are susceptible to a natural limit on their number of cell divisions [58], and whether they have a special mechanism for maintaining telomeres, to avoid programmed cell senescence resulting from critical telomere shortening [59,60] (see also Chapter 6). Both mouse and human HSCs have telomerase activity but telomere length declines in the progeny of HSCs that have undergone a large number of cell divisions [61]. Therefore, the relatively high telomerase activity in HSCs [62] is not sufficient to completely prevent telomere shortening. In the absence of functional telomerase reverse transcriptase (TERT) the progeny of dividing HSCs lose telomeres much more rapidly [61,63].

Transgenic mouse strains that overexpress the TERT component at high levels in HSCs do not reduce the length of their telomeres [64]. Nevertheless, these HSCs still lose transplantation activity after the fourth or fifth serial HSC transplantation [63]. This *loss* of transplantability in HSCs that retain telomeres points to other phenomena limiting the transplantation of these cells, including perhaps the persistent entry into cell cycle, programmed cell life spans independent of telomere length, or random factors associated with transplantation and/or cell division [61,65].

Programmed cell death or senescence of HSCs need not occur only as a result of extensive numbers of HSC cell divisions. There are several genetic loci that regulate, in mice, both the frequency of HSCs in bone marrow and the frequency of HSCs that are in cell cycle [66–68]. One genetic program that likely regulates HSC numbers is that leading to programmed cell death inhibitable by the antiapoptotic proteins MCL1 and BCL2 (and by extension, other antiapoptotic genes such as BCL-x). In mice that have an enforced high level of expression of hBCL2 in HSC, the steady-state levels of HSCs are increased four- to five fold, and the competitive repopulation activity of these HSCs is higher than that of CD45 congenic HSCs transferred into the same irradiated host [69,70].

There are several genes whose expression is required to initiate: hematopoiesis alone, hematopoiesis and angiogenesis, or angiogenesis alone; these include *AML-1/RUNX-1* [71], *SCL-TAL* [72], *FLK1* [73]. At least some of these genes are expressed intrinsically in HSCs [74–79].

Genetic pathways for the self-renewal of HSCs

Self-renewal is the single distinguishing characteristic between LT-HSCs and the rest of the multipotent and oligopotent progenitors in the hematopoietic system (see Chapter 6). For self-renewal to occur for life and for the renewed cells to contribute to hematopoiesis, HSC proliferation must be possible in the absence of differentiation, and life span limitations such as telomere shortening, programmed cell death, and programmed cell removal must be held in check. Several of the genes already found to be involved in HSC functions prohibit differentiation. For example, *BMI1* in the gene expression inhibitor complex PRC1/2 affects H3K27 trimethylation [66,80–82] and inhibition of TET2 and its regulated DNA demethylation pathways [83,84]. In addition, HSCs express higher levels of telomerase and its associated telomere length retention elements,

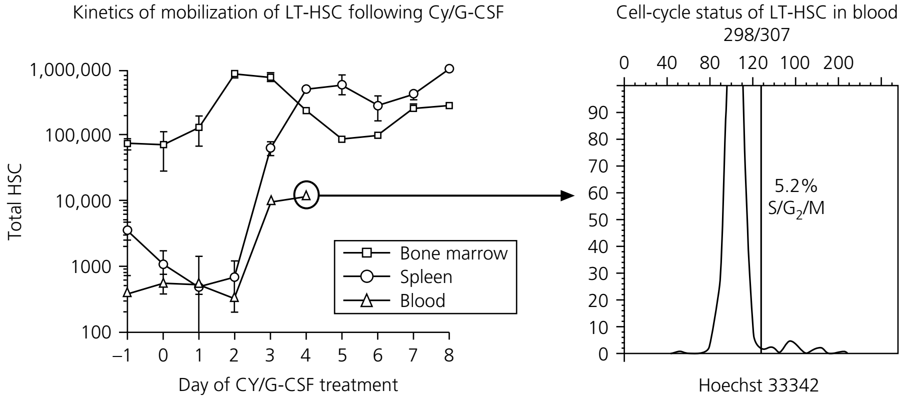

Figure 4.2 The total number of long-term hematopoietic stem cells (LT-HSCs) in the bone marrow, spleen, and blood of mice on successive days of CY/G-CSF treatment. Total bone marrow hematopoietic stem cells (HSCs) were calculated by assuming that the femurs and tibias (less the epiphyses) contained 15% of all bone marrow in the mouse. Total HSC level in the blood was calculated by assuming that the total blood volume was 1.8 mL. Cell-cycle status of LT-HSCs in the blood was determined by Hoechst DNA staining. Source: Wright et al. 2001 [54]. Reproduced with permission of the American Society of Hematology.

and also express antiapoptotic genes such as *MCL1* [85], and perhaps *BCL2* [86]. While LT-HSCs can be expanded in a variety of situations in vivo, the attempt to expand rigorously purified mouse or human HSCs in vitro with conventional cytokines such as steel factor (SLF), thrombopoietin (TPO), interleukin 11 (IL-11), IL-6, IL-3, and Flt3L, alone or in combination in serum-containing medium has never resulted in more than a minor expansion in HSCs by phenotype, and little or no expansion by function [87–93]. Many investigators were led astray by the expansion of cells expressing CD34, but a broad variety of non-HSCs are also CD34$^+$, and these cells were the result of proliferation of HSCs and progenitors coupled with cell differentiation. The introduction of the antiapoptotic protein BCL2 into HSCs in mice allowed HSCs to survive serum-free culture conditions, and so the response of LT-HSCs to factors in the absence of differentiating factors present in serum, such as monocyte/macrophage colony-stimulating factor (M-CSF), G-CSF, granulocyte–monocyte colony-stimulating factor (GM-CSF) and others, could be studied [69,70]. Any combination of these cytokines and others when added to these BCL2-containing HSCs led to a massive burst of proliferation and progenitor expansion by most HSCs, but little or no detectable HSC expansion [69,70]. HSCs responding to IL-3 give large bursts of proliferation with concomitant differentiation along the myeloid and mast cell lineages, without self-renewal of HSCs. One might have hoped that the HSC response to SLF alone would have been self-renewing divisions, as mutations in the *SLF* gene or its receptor, c-kit, lead to fetal or early neonatal morbidity, usually because of profound anemia [94–99] (reviewed in [100]). SLF is a survival cytokine for resting and active HSCs [70], and antibody blockade of its signaling through c-kit can deplete HSCs [101]. However, the response of single highly purified Bcl2-expressing LT-HSCs to SLF in serum-free medium was proliferation without detectable self-renewal, but with differentiation through both common lymphoid and common myeloid progenitor pathways [70]. Stimulation with TPO led to mild proliferation, and dedicated differentiation along the megakaryocytic lineage. Interestingly, analysis of mRNA from HSCs and highly purified myeloid progenitors revealed that HSCs might have the highest expression of the TPO receptor c-mpl, of any of these cell populations [74,102–104, https://gexc.stanford.edu/model/3/gene/Mpl]. TPO is produced by osteoblasts in the bone marrow and blocking antibody to it induces release of HSCs from the niche and their increased proliferation [105]. Together, these data suggest that TPO is important for HSC proliferation and self-renewal after transplantation but also promotes quiescence by promoting retention in the niche, with increased integrin expression and prevention of cycling and subsequent HSC exhaustion.

Some early experiments indicated that other factors may be involved in HSC expansion. For example, activation of the Notch-1 receptor mimicked by retroviral transduction with the intracellular activated form of Notch-1 occasionally led to the generation of mouse cell lines with many of the characteristics of HSCs, although this response was neither general nor robust [106,107]. Provision of *HoxB4* as a retroviral insert in semipurified mouse hematopoietic progenitors led to vigorous proliferation and at least some retention of hematopoietic multilineage and long-term reconstituting activity in vitro and in vivo [108–110]. However, there has yet to be a rigorous demonstration that this outcome was caused by expansion of HSCs alone, rather than by provision of other signals that enable their engraftment [109–111].

The Wnt/Fzd/Dsh/GSK-3β/β-catenin pathway is also implicated in HSC self-renewal (reviewed in [112,113]). Wnt, a highly hydrophobic protein binds to surface frizzled (Fzd), a 7TM protein, in combination with a low-density lipoprotein-associated receptor, usually low-density lipoprotein receptor-related protein (LRP) 5. Binding of Wnt to Fzd leads to activation of disheveled (Dsh). The action of Dsh allows β-catenin to dissociate from the complex that includes APC, axin, and GSK-3β; this prevents GSK-3β phosphorylation of β-catenin, which, therefore, can translocate to the nucleus, where it becomes available for binding to Lef/TCF DNA binding transcription factors to activate transcription [112,113].

The addition of partially or fully purified Wnt3A to highly purified LT-HSCs in serum-free medium results in clonal proliferation of HSCs. In vitro, these HSCs go through a significant expansion and up to 50% of the expanded progeny are cells of the LT-HSC phenotype [114,115]. Transfection of non-degradable β-catenin lacking the *N*-terminal phosphorylation sites were reported to drive LT-HSC into massive and prolonged expanding cell divisions, with expansion of LT-HSCs both by phenotype and by function upon transplantation [114]. Inhibitors of Wnt signaling even blocked SLF and other cytokine-mediated proliferation of LT-HSCs [114]. When LT-HSCs are transfected with a reporter of LEF/TCF + β-catenin activity in the nucleus and then transplanted into lethally irradiated hosts, LT-HSCs reading out the reporter are retained in vivo long term, whereas myeloid progenitors derived from these LT-HSCs do not express the reporter [114]. Taken together, these results indicated that the Wnt/Fzd/β-catenin pathway is likely important in self-renewing cell division of LT-HSCs. When activated by Wnt3A, LT-HSCs upregulate expression of both *Notch-1* and *HoxB4*, genes also implicated in the self-renewal of HSCs. However, the regulated deletion of the β-catenin gene in transplanted bone marrow failed to affect the engraftment of hematopoiesis or the retransplantation capacity of this marrow [116]. Contradictory results were recently reported with a different gene promoter encoding the Cre recombinase required for β-catenin deletion [117].

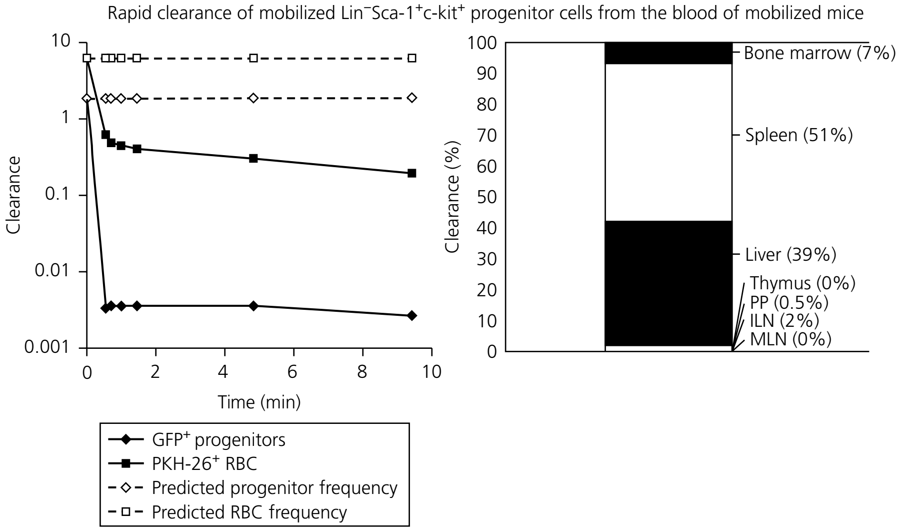
The *BMI1* gene is a member of the polycomb family, which has a role in silencing gene expression by site-specific deacetylation of histones associated with those genes, as well as trimethylation of H3K27 [80]. *BMI1* is expressed at high levels in mouse and human LT-HSCs, and mice with an artificially mutated *BMI1* gene have a profound defect in the transplantation and self-renewal of LT-HSCs [78,80]. The two transcripts of the p16 locus, P16INK4A and P19ARF, are overexpressed selectively in the hematopoietic tissues in the *BMI1*-mutant mice, thus indicating a role of *BMI1* in down-regulation of genes whose expression could lead to differentiation and/or is contrary to self-renewal of HSCs [118]. These anti-self-renewing effects could include decreased viability, enforced differentiation, or direct regulation or inhibition of genes involved in the self-renewing pathways such as those of Wnt/Fzd/β-catenin and Notch [106,107,112,114]. *BMI1* mutants show no differences in expression of *HoxB4* but an increase of *HoxA9* [80], genes that also have some role in HSC functions [111,119].

JunB negatively regulates mouse LT-HSCs, and in the absence of JunB the HSC pool expands. In the expanded pool, p16ink4a and p19arf are expressed at lower levels than wild-type HSC, and bcl2 and bclxl are expressed at higher levels in JunB knock-out HSCs than in wild-type HSCs [120]. A number of genes have recently been reported to play a role in HSC self-renewal, including *JunB*, *Sox17*, *Cited2*, *Mcl1*, *Tel/Etv6*, *Gfi1*, *Pten*, and *Stat5*. Chapter 6 covers self-renewal in more detail, but, taken together, these results indicate that the control of self-renewal is a complex, multipathway process, much of which is probably controlled by the HSC niche.

Migration of HSCs

Hematopoietic capacity is known to be present in the adult mouse at the highest levels in bone marrow, at about one-tenth of that level in the spleen, and at 1/100 of the bone marrow level or less in blood [121]. In the early experiments that showed this, the ability of marrow or tissue transplants to retain erythropoiesis could not be assigned directly to the action of HSCs. There was no clear explanation as to why hematopoietic activity might be present in organs other than the bone marrow, and certainly not in the blood. It was only when clinical hematopoietic cell transplantation groups described the phenomenon of hematopoietic activity increasing in the blood of cytotoxic drug-treated individuals that the possibility of HSC mobilization into the blood was considered [122,123].

Empirical protocols using cyclophosphamide plus cytokines such as G-CSF, GM-CSF, SLF alone or in various combinations with G-CSF, IL-1, IL-3, led to efficient mechanisms to mobilize hematopoietic cells into the bloodstream [124–128]. In these early experiments, this activity was measured in terms of *in vitro* tests for hematopoietic colony-forming cells (CFCs), but CFC assays alone are not specific for HSC versus oligolineage progenitor activities [36,129]. However, there could be no doubt that HSCs were involved when MPB transplants were used in hosts conditioned with high-dose chemotherapy, resulting in both early and sustained hematopoiesis. When cyclophosphamide and G-CSF are used in the mouse model – wherein one can analyze directly the daily changes in marrow, spleen, and blood – it is clear that nearly every HSC and MPP enters cell cycle rapidly [56]. These reach a peak in the marrow, at which time the cells appear rapidly in blood and spleen (Figure 4.2). At all times the HSCs appearing in the blood have 2N amount of DNA, indicating that they are not proliferating in the blood; in fact, the fold increase in their numbers would have ruled out a blood-only expansion of the HSC pool [56]. Bromodeoxyuridine (BrdU) incorporation into their chromosomal DNA during the expansion phase of HSCs in the "mobilized" bone marrow results in the labeling of virtually every HSC and, interestingly, just 1 or 2 days later, the 2N HSCs found in the blood are all labeled with BrdU [56]. Thus, mobilization appears to be a consequence of marrow HSC proliferation and accumulation of emigrant HSCs in extramedullary sites such as spleen, liver, and blood. HSCs have low levels of receptors for G-CSF [102,103,130], yet G-CSF triggers mobilization of highly purified HSCs [131,132]. In the early phases of mobilization, there is a rise in cells of the myelomonocytic series, and it has been shown that the elaboration locally by myeloid cells of matrix metalloproteinases such as MMP9 can serve to cleave cell–cell interaction molecules known to be active between HSCs and marrow stroma [133]. Similarly, elaboration of the chemokine IL-8 occurs and infusion of IL-8 alone can cause a significant and rapid mobilization of HSCs [134,135]. The actual nature of molecules involved in HSC release is not clear, although it is known that HSCs express integrin $\alpha_4\beta_1$, which allows them to attach to hematopoietic stromal cell VCAM-1 [136–140]. Also, HSCs express the c-kit receptor, which allows binding to at least cell-surface SLF on stroma. Although HSCs have a number of other members of the adhesion and integrin family, the role of each of these in the following remains unclear: cell proliferation, detachment from stroma, local emigration into sinusoids, movement through the bloodstream, margination on distant blood vessels, transendothelial migration at these vessel sites, and localization to microniches that support LT-HSCs. In the adult mouse, homing of infused HSCs appears to involve both cell surface integrin $\alpha_4\beta_1$ and cell surface CXCR4, a receptor for the chemokine SDF-1 [141–143]. Of all known chemokines, SDF-1 is the only one to which adult mouse HSCs migrate in vitro, and this is chemotactic movement [143]. However released, co-infusion of labeled HSCs and labeled red blood cells (RBCs) from mobilized blood into the blood of same-stage mobilized animals results in the rapid emigration of HSCs out of the blood and these HSCs do not reappear in the bloodstream for the next several hours (Figure 4.3). These HSCs non-randomly home to hematopoietic sites in mobilized animals: bone marrow, spleen, and liver – all tissues with sinusoids lined by macrophages. These observations fit with previous studies on the rapid egress of infused lymphocytes out of the bloodstream into tissues via recognition of particular vascular addressins for which they have cognate homing receptors [144,145]; and the rapid egress from



Rapid clearance of mobilized Lin$^-$Sca-1$^+$c-kit$^+$ progenitor cells from the blood of mobilized mice

the bloodstream of other nucleated cells such as monocytes [146]. There are similar HSC, MPP, and myeloid progenitor fluxes in normal mice. Maintenance of the approximate 10–100 HSCs found in the blood of mice, given a residence time in the blood of 5 min or less, would require fluxes of well over tens of thousands of HSCs and MPPs per day. Data suggest that HSCs and progenitors circulate through the blood and reside in the tissues for up to 36 hours before returning to the blood via the lymphatics [147]. It is not yet clear whether these cells are passing through the blood in one pass or whether they form a specialized pool of HSCs and MPPs that have a higher probability of reentering the blood than cells resident in deep marrow niches. If HSCs found in the blood are also derived from dividing HSCs, nearly one out of every two daughter cells from a self-renewing HSC division would have to enter the bloodstream.

Consistent with this emigration rate, infusion of purified LT-HSCs into untreated immunodeficient mice (to avoid immune rejection of cells with antigenic markers) led to a dose–response engraftment of marrow sites with 0 to 250 HSCs, while up to 5000 infused HSCs engrafted no more marrow sites than did 50 infused HSCs. This plateau was about 0.5% of marrow sites. However, 50 cells on day 1 and another 50 cells on day 2 each engrafted about 0.5% of the marrow sites [148]. Thus, about 0.5% of the marrow niches for HSCs appear to be available at any moment, and these appear to be occupied by the next interval. Pre-clearing of HSCs with a cytoreductive anti-c-kit antibody alone in immunodeficient mice leads to up to 80% engraftment with purified HSCs given in large numbers at the point that the mAb reaches its lowest concentration in the blood [101].

The migration of HSC into hematopoietic tissues involves a step of crossing macrophage-lined sinusoids. During mobilization, HSCs and progenitors upregulate the expression of the integrin-associated protein CD47 [149]. One function of CD47 is as a ligand for the SIRPα macrophage receptor [150]. In the absence of CD47, macrophage-bound cells are phagocytosed, whereas cells expressing high levels of CD47 signal the macrophage through SIRPα to block phagocytosis. We have found that leukemias transfected with mouse CD47 at levels approximating those found on mobilized HSCs are protected from phagocytosis in vitro and engraft in vivo, whereas the same leukemias lacking these levels of CD47 are phagocytosed in vitro and fail to engraft in vivo [149]. Further, HSCs from CD47-knockout mice fail to engraft in wild-type congenic mice [149]. These experiments provide evidence that, during migration, itinerant HSCs express high levels of CD47 to gain entry to hematopoietic sites.

Hematopoietic stem cell and progenitor niches

Interpreting the fate of recently self-renewed and resting HSCs calls for a deeper examination of hematopoietic niches in the marrow. Niches that commit recently entering HSCs to the myeloid or lymphoid pathways need not be adjacent to the HSC niche from which the parent, uncommitted HSCs came if the daughter cells are constantly migrating. In addition, a large flux of recirculating HSCs likely provides for the continuous replacement of empty HSC niches with functional HSCs. In the absence of such a pool of migrating HSCs, the death of an HSC could mean the permanent loss of that functional niche. This finding has relevance when one considers claims of plasticity of stem cells in one or more tissues [48]. If tens of thousands of HSCs are fluxing through tissues every day, finding HSC activity in those tissues might result only from these itinerant HSCs, rather than transdifferentiation of local tissue-specific stem cells into hematopoietic fates [48].

The understanding of the anatomical sites for HSC niches followed hypothetical analyses of the need for such niches to control HSC numbers and to account for their differentiation to progenitors. Schofield proposed that such niches would be most likely placed next to bone [151], and several later studies showed that a subset of osteoblast-lineage cells likely were part of the niche [152,153]. Much earlier, Dexter et al. developed bone marrow stromal cultures that supported myeloerythropoiesis [22,154], and Whitlock and Witte developed stromal cultures that supported B lymphopoiesis [155]. Whitlock et al. cloned single stromal cells from these cultures, and developed several stromal lines, some of which supported only myeloerythropoiesis, and others, myeloid production followed by B lymphoid production [156]. For both of these types of cultures, only HSCs could initiate long-term cultures [155,156] that included B and myeloid outcomes from single cells. The stromal cell clones that allowed single HSCs to produce multiple lineages expressed several surface markers, including 6C3/Bp1, a transmembrane protein with an ectodomain peptidase that is expressed on early B lineage progenitors [157] and is induced by IL-7 on these stromal and B lineage cells [158]. The prospective isolation of mouse and human HSCs used one such clone, AC6.2.1, in the readouts of multilineage precursors. Both Dexter and Whitlock-Witte cultures gave accurate readouts of mouse and human HSCs and hematopoietic progenitors and the adhesion molecules, for example integrin $\alpha_4\beta_1$ with VCAM-1 [23,136,137,158], that these stem and progenitor cells use to bind to the stroma. The lines that support myelopoiesis often have hematopoietic cultures that overgrow with macrophages, and a line from the CSF-1 osteopetrotic mouse, OP9, supports myelopoietic cultures over the long term [159]. The modern approaches to the cellular components in the hematopoietic marrow niche now include at least three cell lineages, the osteoblast subset [160], a nestin$^+$ stromal cell innervated by SNS peripheral nervous system neurons [161], and blood vessel cells [162]. Programmed knockdown of genes in the endothelial lineages leads to diminution of HSC levels.

Dissociated cells from early mouse fetal bone, taken prior to the seeding of hematopoiesis at embryonic-day (E)15, transplanted in matrigel ectopically under the kidney capsule form new bones, with cartilage components and complete intraosseus bone marrow, with blood vessels, blood lineage cells, and HSCs from the host [163]. Prospective isolation of a clonal precursor that self-renews and forms bone, cartilage, and at least four distinct hematopoietic supporting stromal cells has been accomplished [163,164]. The stroma include 6C3$^+$ cells with similar profiles to the AC6.2.1 population that was clonally isolated from Whitlock-Witte cultures 26 years ago [164]. These newly isolated cells support HSCs to conduct full hematopoiesis and self-renew in vitro. They also contain mRNA encoding Wnt4 and CXCL12, while a separate subset expresses cell surface CD90 and includes mRNA expressing SLF. Intravenously infused pure HSCs can be found in cavities bounded by the 6C3$^+$ and the CD90$^+$ stroma, neither of which are on the surface of osteoblasts or endothelial cells [164]. Taken together, these studies indicate the existence of a very complex mouse niche with multiple stromal cell types and segregated expression of HSC-supporting cytokines.

Ontogeny of HSCs

It is tacitly assumed that HSCs derive from the embryonic mesoderm. In mammals, the first site of definable blood cells appears to be the yolk sac blood islands, in mice at about 7.5 days post-coitum (dpc) [165,166]. At 7–8 dpc, mouse yolk sacs contain cells capable of responding in vitro to produce hematopoietic CFCs [165,166]. The yolk sac connects to the developing embryo/fetus [167] at about 8.5 dpc via the development of the vitelline vessels, which feed into the embryo proper. Just after that 8–8.5 dpc interval, hematopoietic cells appear in and around the dorsal aorta of the developing fetus (reviewed in [168]). Nearly 40 years ago, we showed that transplantation of 8–9-dpc yolk sac blood island cells into the yolk sac cavity of 8-dpc allogeneic hosts results in mice that have lifelong presence of donor-derived day 10 CFU-S in marrow as well as thymocytes [169]. At about 10–11 dpc, hematopoiesis begins in the fetal liver in the mouse, and continues there throughout fetal life.

Where do the first HSCs develop [170]? At 3.5 dpc, the blastocyst implants into the uterus, and its inner cell mass appears to be a population of pluripotent cells without defined commitments [167]. Between 3.5 and 5.5 dpc, gastrulation occurs with the formation of the three germ layers [167]. It has been a mystery whether the developing post-gastrulation mesoderm cells emigrate separately to yolk sac and embryo to give rise to independent origins of hematopoiesis; or whether only one of these sites is the initial site of commitment to hematopoiesis, and the other sites that appear later result from migration [168,169,171,172]. The idea of separate origins for extra-embryonic (yolk sac) hematopoiesis and intra-embryonic hematopoiesis was supported by the fact that yolk sac erythropoiesis produced embryonic and fetal hemoglobins, while lifelong hematopoiesis produced mainly adult hemoglobin [171,173]. These were called, respectively, primitive and definitive hematopoiesis [173]. Until 2007, no experiment directly assessed whether these two kinds of hematopoiesis have distinct or common origins at the cellular level. To address this question Nishikawa's group used an inducible Runx1/aml1 reporter system to label extra-embryonic HSCs [174]. When embryos were induced at 7.5 dpc, the time that HSCs first appear in the yolk sac blood islands [169,175], labeled hematopoietic cells were observed in the fetus and adult. As circulation was not established at this time-point, these data suggest that the labeled HSCs that persist and give rise to ongoing hematopoiesis must have derived from yolk-sac HSCs that migrated into the embryo once circulation was established [174]. Because the placenta and the allantois at 9 dpc have some Runx1$^+$ cells, they are other possible sites of HSC generation in these experiments if the tamoxifen inducer has a half-life in the embryo greater than a day.

Hematopoiesis and angiogenesis are closely associated in both the developing blood islands and the developing dorsal aorta, and there is good evidence that mutant mice lacking the cell surface receptors for angiogenic peptides fail to develop either hematopoietic or angiogenic cells [73,176]. While these experiments suggest that a bipotent precursor called the hemangioblast exists that can give rise to both angiogenic stem cells and HSCs, only a small number of hemangioblast cells capable of producing both outcomes in vitro can be prospectively isolated from the pre-yolk sac embryo [177]. Rather than there being a hemangioblast precursor, it is possible that mutant mice that cannot make blood vessels properly, cannot make blood because primitive stem cells travel via the blood, or that blood vessels make factors important for hematopoiesis. Nevertheless, there are several independent studies that show the existence of hemogenic endothelial cells in mice [178] and zebrafish [179]. Whether the progeny of cells that appear to bud from hemogenic endothelium is the HSC or some other cell type is still unclear.

A set of our experiments supports the hypothesis that the majority of embryonic blood cells found in yolk sac blood islands do not share a clonal progenitor in the yolk sac, and therefore many derive from pre-hematopoietic mesodermal cells in the yolk sac [180]. Tetrachimeric mice were generated by injection of four distinctly colored single cells into developing blastocysts. Analysis of the color combinations observed in the yolk sac of the resulting embryos revealed endothelial and hematopoietic cells of different colors in all individual blood islands, indicating that they developed from more than one cell (Figure 4.4). If both hematopoietic and endothelial cells derived from a common hemangioblast progenitor, each blood island would be monochromatic in these mice. However, single-color blood islands were not observed. Instead the majority of blood islands contained blood and endothelial cells of multiple but not necessarily the same colors, indicating that multiple progenitors of each type came together to form each blood island [180]. About 15–20% of the blood islands examined could have derived from hemangioblasts; when we lineage-marked cells with the Flk1.cre/floxed Lacz$^-$GFP constructs in the same ES cells, about 20% of blood cells were GFP$^+$, indicating an activated Flk1 locus, but 80% were Lacz$^+$GFP$^-$. These data indicate that about 20% of early blood cells derive from a possible hemangioblast progenitor, and about 80% derive from a hematopoietic progenitor that did not go through a hemangioblast pathway. Similar conclusions were drawn by Shalaby et al. [73]. However, Choi et al. report that all yolk sac cells are derived from Flk1$^+$ precursors [181], a finding different from ours.

There is an interesting point coming out of embryonic stem cell biology that may be relevant to these issues. ES cells are derived from the inner cell mass of blastocysts, and likely represent pluripotent stem cells in the mouse at approximately 3.5 dpc. They are maintained as pluripotent cells by the addition of LIF (leukemia inhibitory factor) to their cultures, at least in mouse ES lines [182]. Removal of LIF from these pluripotent ES lines results in the onset of hematopoiesis and, during this development, 5 to 8 days after LIF was withdrawn, cells capable of in vitro hematopoiesis emerge. These cells also express some markers (AA4.1$^+$c-kit$^+$CD34$^+$Lin$^-$CD41$^+$CD45$^+$) shared with HSCs, but at this point are Sca1$^-$ [183]. Yolk sac blood island cells at 9 dpc are also AA4.1$^+$c-kit$^+$CD34$^+$Lin$^-$cD41$^+$CD45$^+$ [169,175]. Thus, these two systems appear in parallel to produce embryonic HSCs. However, the ES derived "HSCs" express adult hemoglobin, and can produce myeloerythroid and lymphoid cells. Despite this, ES-derived HSCs did not engraft in irradiated newborn or adult hosts [183], indicating the requirement for further development of these cells to give rise to transplantable HSCs. HSCs are in far greater numbers at all times in the yolk sac blood islands than in the embryo proper (e.g., within the dorsal aorta) [183,184]. While the numbers of HSCs in the yolk sac at all times could support the number of HSCs found in 11.5-dpc fetal liver, the number in the embryo proper in the entire dorsal aorta could only supply a fraction of those in the 11.5-dpc fetal liver. These findings indicate that yolk sac blood island cells represent a site of both embryonic and definitive hematopoiesis.

The major site of the next (fetal) stage of hematopoiesis, after the yolk sac blood islands, appears to be the fetal liver [166]. The numbers of HSCs in the fetal liver increase logarithmically from 11–15 dpc. After 15 dpc, fetal liver HSC numbers level off, but hematopoiesis continues to expand in the liver [33,185,186]. At 16 dpc, hematopoiesis appears in the fetal spleen in mice, and at 18 dpc, in the fetal bone marrow.

The initiation of fetal liver hematopoiesis is blocked in mice with mutations in integrin $\alpha_4\beta_1$ (VLA-4) or integrin $\alpha_5\beta_1$ (VLA-5) [187,188]. Because integrins are involved in cell migration, immigration of

these cells into or beyond the fetal liver may require steps that include expression of $\alpha_4\beta_1$ or induce the expression of integrin $\alpha_5\beta_1$ at this stage of the liver. Integrin $\alpha_4\beta_1$ is used by trafficking HSCs throughout life to enter sites of hematopoiesis [140], and so the endowment of expression of integrin $\alpha_4\beta_1$ permits fetal liver HSCs to be assayed by transplantation in fetuses or adults. In contrast, neither yolk sac blood island HSCs nor ES-derived HSCs in their native state can be transplanted into adult irradiated mice. The transition of yolk sac HSCs and ES-derived HSCs from that embryonic stage to the fetal stage reportedly can be facilitated by enforced expression by *HoxB4*, or by *HoxB4* and *Cdx4* in these cells [108]. Therefore, there are important clues to how embryonic HSCs, presumably capable of primitive hematopoiesis, can develop into fetal HSCs capable of definitive hematopoiesis.

During the various stages of fetal HSC functions, it initially seemed possible that waves of HSCs emerged from tissues such as the fetal liver at specific time points to be accepted by and to engraft in secondary sites such as fetal spleen, fetal bone marrow, and lymphoid sites such as the thymus [170]. However, HSCs are found constitutively in the blood throughout fetal life, and it must be the preparedness of the developing organs such as the spleen, marrow, and thymus that results in the movement of hematopoiesis to those sites [189].

A detailed examination of HSCs in the developing fetal liver with respect to T-cell developmental potentials has revealed that changes are occurring at the level of HSCs which show that HSCs develop in a quantal but dynamic process [190]. Developing T cells gain their specificity and their function in a coordinated series of molecular events, including selection of which class of T-cell receptor genes are rearranged and selected, and to which distant sites the T cells will migrate. Within the thymus, during fetal development, the first T cells to emerge use products of the T-cell receptor Vγ3 and T-cell receptor δ gene families, followed by the T-cell receptor Vγ4, then Vγ2 and Vγ5 and T-cell receptor $\alpha\beta$ gene families. In mice the T-cell receptor V genes at the γ locus that must rearrange to be expressed are, extending from the most proximal site of potential rearrangements, Vγ3, Vγ4, Vγ2, and then Vγ5. The first T cells to emerge in the thymus are Vγ3 cells, which colonize the skin only during fetal life [191]. While Vγ3 T-cell development is shutting down in the thymus, Vγ4 T-cell development arises, and these T cells will migrate during fetal life to the presumptive female genital tract epithelia and the tongue epithelium of both sexes [190,191]. The development of Vγ4 T cells decreases at about day 16 or 17 of fetal life, to be overtaken by the almost simultaneous onset of: Vγ2 T cells, which will inhabit lymph nodes and secondary lymphoid sites such as the spleen; Vγ5 T cells, which will inhabit the entire gastrointestinal tract; and αβ T cells, which are largely restricted to lymphoid tissues.

The kinetics of T-cell development can be studied with the use of fetal thymic organ cultures (FTOCs), although these are not physiologic cultures. When single clonogenic 12-dpc fetal liver HSCs are added to FTOCs, those thymuses produce Vγ3, then Vγ2, then Vγ5, and TCRαβ T cells [190]. When 14-dpc fetal liver HSCs are placed at clonal levels into the same stage FTOC, Vγ3 T cells do not emerge, but the rest of the repertoire is developed. Finally, 12-dpc fetal liver HSCs added directly into the adult thymus cannot produce the fetal program of Vγ3 T cells, but can produce the mature program of Vγ2, Vγ5, and TCRαβ cells [190].

Taken together, these studies indicate that, probably with each cell division, the fetal liver HSCs are changing (usually reducing) their developmental fates, which would only be read out when their progeny entered the fetal thymus, and the change in these fates and the readout of these fates is dependent upon factors within HSCs and within the thymus microenvironment. After birth, and at least in young adult mice, the numbers of LT-HSCs, ST-HSCs, and MPPs are regulated at a relatively constant level.

The aging of HSCs: clonal selection versus regulated epigenetic change

HSCs in the mouse go through cell autonomous changes in numbers and developmental potentials during aging. We first reported that there is a gradual loss of cells of the MPP phenotype and an increase in both the number of LT-HSCs and the fraction of LT-HSCs that are in the cell cycle [65], most dramatically seen in the marrow of geriatric mice. With a refinement of markers for LT-HSCs versus all other multipotent progenitors, we found that the number of LT-HSCs increased as reported, but that they retained a low level of cell-cycle activity; the increase was found primarily in a MPP fraction [77]. In old mice, myelopoiesis is retained or even enhanced, while lymphopoiesis in both T- and B-cell lineages falls. These fates are cell intrinsic; co-transplantation of 2-month-old and 2-year-old LT-HSCs into irradiated young mice led to increased output of LT-HSCs from the old versus young stem cells, and less output of CLPs and T and B cells from the old LT-HSCs than from the young LT-HSCs [77]. These same trends were seen in the small number of aged hosts transplanted with young and old HSCs. The cell intrinsic biologic properties of old versus young HSCs were mirrored by a microarray analysis of these highly purified cells: young HSCs had both myeloid and lymphoid transcripts, but old HSCs overexpressed myeloid and underexpressed lymphoid transcripts [77]. Of the top 32 myeloid transcripts overexpressed in old HSCs, 13 have been identified as proto-oncogene or translocation partners of myelogenous leukemia proto-oncogenes in humans. As myelogenous leukemias increase in incidence with age, the initiating events may occur in HSCs, and if they do, genomic events such as translocation and inversion may occur preferentially at highly transcribed loci.

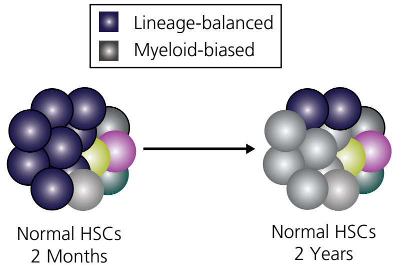

Figure 4.5 At birth, most of the hematopoietic stem cell (HSC) clones in mice are *lineage-balanced*, that is, equally capable of generating various lineages. However, with age, clones biased towards generating myeloid lineages (*myeloid-biased*) predominate, due to either clonal selection or epigenetic changes in the originally lineage-balanced clones. (For a color version of this figure, please see the color plate section.)

In aged mice with predominantly myeloid-biased HSCs the majority of HSCs are CD150^{hi}, while in young mice the majority are CD150^{lo-med}, with rare CD150^{hi} cells. CD150^{hi} HSCs from young or old mice are myeloid biased, while CD150^{lo-med} cells from young or old mice are balanced or lymphoid biased at the single cell level [192]. This opens the possibility, shown in Figure 4.5, that mice are born with various clones of HSCs with preset hematopoietic potentials, and that during aging, the myeloid-biased subset outcompetes the balanced or lymphoid-biased clones. Since the same distribution of myeloid-biased versus balanced HSCs is found in human bone marrow – balanced in youth but with a dominance of myeloid-biased cells in the elderly [193] – it appears that this is an evolutionarily conserved phenomenon. We speculate that before trains, planes, and cars, most species encountered the microbes in their microgeography by puberty, giving rise to long-lived memory T- and B-cell clones against them. Therefore the demand for naïve immunocompetent T and B cells is diminished, and the need for the continual generation of CLPs that give rise to them also decreases as the myeloid-biased HSC clones become dominant in the aged.

Does hematopoiesis only derive from HSCs and do HSCs give rise only to blood?

Several years ago, there were reports that bone marrow hematopoietic cells could give rise to brain cells, that brain stem cell populations can give rise to blood, that fat cells can give rise to neurons and mesenchymal cells, that muscle stem cells can give rise to hematopoietic and myogenic outcomes, and a host of other types of transdifferentiations (reviewed in [194]). What was lacking in most of these experiments was the demonstration that the transplanted population was in fact a stem cell purified to homogeneity that could give rise at the clonal level to two different tissue types, and that the tissue types that had been generated were robustly characterized as functional mature cells of that tissue without cell fusion.

Attempts to repeat the experiments showing transdifferentiation of CNS stem cells to hematopoietic tissues have thus far failed. A reexamination of the cells in muscle that give rise to blood show them to be CD45^{+} committed HSCs, separable from muscle progenitors that, on their own, give rise to muscle [195,196]. In some circumstances, regenerating muscle following an injury can incorporate cells whose markers are expressed in the regenerated muscle tissue, and the most common transplantable source of these cells is bone marrow [197,198]. While some claims have been made that these are derived from HSCs, in fact single purified HSCs, even over long intervals, cannot contribute to muscle or any other tissue [48]. In another example, hepatocytes bearing markers from injected purified HSCs regenerated, following multiple rounds of selection through liver toxicity [199]. However, recent evidence [200,201] indicates that these regenerated hepatocytes are mainly a result of rare cell fusion events between myelomonoctic progeny of the hematopoietic stem cells and some precursor of liver cells. In studies of neural tissue, the marrow cells or HSCs or circulating precursor cells that enter undamaged or kainite-damaged brains have limited fates as microglia and $CD45^+$ cells, as well as rare binucleate Purkinje cells derived by cell fusion [202]. Following the studies arguing for transdifferentiation, reports again were published supporting the possibility of pluripotency in non-germline cells in postnatal mammals. These reports claimed that true pluripotent cells exist in adult bone marrow and blood, and are $CD45^-$ "very small" (3–5 μ) embryonic-like stem cells [203,204]. We found no such pluripotent cells in mouse blood or marrow [205], and others have been unable to find them in human hematopoietic tissues [206].

The many claims that transdifferentiation could occur reflect a problem in stem cell biology as a young field. Most new investigators to the field did not appreciate the importance of purifying the populations to homogeneity, populations of cells of apparent phenotypic and functional homogeneity, and did not mark cells retrovirally or with other genetic markers to follow the fate of clonogenic precursors.

The transition from discovery to accepted scientific fact

It is important to note that for a reported discovery to become accepted as scientific fact, the following several criteria need to be met:

1. The initial discovery must be published in fully peer-reviewed journals.
2. The experiment as published must be repeatable in many independent laboratories.
3. The phenomenon described should be so robust that other experimental methods must reveal it.
4. In the case of transplantation, the tissue regeneration must be therapeutic in quantity and quality.

Based on these criteria, we do not believe there is sufficient evidence for the claims that tissue-specific stem cells in a postnatal organism can transdifferentiate and, upon transplantation, generate another tissue. In addition, bone marrow is not the same as HSCs, but is a population of mature or maturing cells, and certainly includes at least two or three stem and progenitor populations: HSCs, mesenchymal stem (more accurately, stromal) cells (MSCs), bone and cartilage lineage cells, and endothelial cells. Thus, it is inappropriate for such initial claims of transdifferentiation to be considered true enough to be the basis of clinical trials or care protocols or public funding and policy decisions.

Lineage committed hematopoietic progenitor cells

Considerations for the definition/isolation of hematopoietic progenitors

The developmental process from HSCs to mature cells must involve intermediates that have lost stem cell potentials but are not yet terminally differentiated. An important question and active area of research regards the sequence in which lineage commitment occurs. Several findings suggested the existence of oligopotent progenitors. First, the lack of both T and B lymphocytes in patients with severe combined immunodeficiency syndromes (SCID) was taken as evidence for the existence of oligopotent, lymphoid-committed progenitor cells or lymphoid stem cells. However, the loss of lymphocytes caused by adenosine deaminase (ADA) deficiency [207,208] or by mutations of the common cytokine receptor γ-chain (γ_c) [209,210] does not necessarily imply a common progenitor. Rather, several lymphoid cell types or their progenitors may be most susceptible to the induced alterations [211] or may be dependent on the same signal transduction mechanisms. This same caution needs to be applied to the interpretation of hematopoietic phenotypes of genetically altered mice, as mutants of Ikaros [212] or Notch-1 [213] that could either be essential factors for common or multiple different progenitors [214].

Second, leukemia cells can be viewed as cells that are arrested at early developmental stages but have gained self-renewal capacity. The occurrence of leukemias that either co-express antigens normally associated with myeloid or lymphoid cell types (mixed lineage leukemias) or that harbor two leukemia populations of clonal origin (bilineal leukemias) could be taken as evidence for the existence of bipotent B-myeloid or T-myeloid progenitors [215–220] (or reviewed in [221–223]). However, leukemia clones could be derived from HSCs, from MPPs, or from restricted progenitors that, because of their altered gene expression profile, display cell surface gene products that are normally not present at these developmental stages.

Third, the fact that single cells in bone marrow give rise to colonies that contain all myeloid but no lymphoid progeny in vitro (colony-forming unit – granulocyte/erythrocyte/macrophage/megakaryocyte, CFU-GEMM) or in vivo (mixed CFU-S) suggests the existence of oligopotent myeloid progenitors. However, cells that give a myeloid readout could also be multipotent but did not find the conditions to read out all possible progeny [23,224,225].

In light of these problems, several prerequisites need to be met to define restricted progenitors in a developmental hierarchy. First, to prospectively identify candidate populations, they need to be isolated to the highest possible homogeneity/purity. Second, if a population shows oligopotent differentiation activity, it must be demonstrated that at least some single cells within this population give an oligopotent readout, that is, that this population is not a mixture of different monopotent progenitors. Third, it needs to be shown that single oligopotent progenitors are not HSCs or MPPs. These prerequisites are difficult to achieve. At any given time point, progenitor cells may undergo intrinsic "stochastic" commitment events, may not find suitable microenvironments to read out all their possibilities, or may even not read out at all [226,227]. However, by applying the above criteria, we and others were able to identify oligopotent developmental intermediates in mice and humans. These data strongly support the hypothesis that multipotent hematopoietic progenitors first lose their self-renewal ability and consecutively commit to either the lymphoid or myeloid developmental pathway. Although not formally proven, based on frequency, cycling status, and in vitro and in vivo expansion potential of bone marrow lymphoid and myeloid committed progenitors, it seems possible that all hematopoiesis develops through either a common lymphoid or common myeloid developmental stage.

Common lymphoid progenitor cells and lymphoid development

Lymphoid cell development from HSCs is dependent on externally provided differentiation, growth, and survival factors. Of those, IL-7 may be most important. Its cognate high-affinity receptor is a complex composed of the IL-7Rα chain [228] and the γ$_c$ chain [210,229]. Neutralizing antibodies to IL-7 or genetic ablation of either IL-7 or IL-7Rα inhibit both T- and B-cell development in vivo [230,231]. Targeted deletion of the γ$_c$ gene leads to the loss of T and B cells and the additional loss of natural killer (NK) cells [232–234], presumably because of the impaired formation not only of the IL-7R, but also the IL-2R and IL-15R that may be non-redundant cytokines for NK cell development [235–237]. Furthermore, mice that lack Jak3, a signal transduction molecule associated with γ$_c$ [238,239], display a similar phenotype as the γ$_c$-deficient mice [240–242]. Also, patients with genetic defects in Jak3 show similar defects in lymphoid development as patients with γ$_c$ gene disruptions (X-SCID) [243,244]. Based on these data, IL-7 is recognized as a non-redundant cytokine for both T- and B-cell development that could act as a proliferation factor, a survival factor, and/or could initiate lineage-specific developmental programs. IL-7R is expressed on both developing T and B cells, and in mature T cells [245]. In genetically modified mice that are either IL-7Rα$^{-/-}$, γ$_c^{-/-}$, or IL-7$^{-/-}$, T-cell progenitors express low levels of Bcl-2, an antiapoptotic protein [246]. However, incubation of T cells from IL-7$^{-/-}$ mice with recombinant IL-7 results in the upregulation of Bcl-2 [247], and enforced expression of Bcl-2 in either IL-7Rα$^{-/-}$ or γc$^{-/-}$ mice leads to significant rescue of αβ T-cell development [247,249]. Therefore, a critical role of IL-7 in developing and mature αβ T cells is the promotion of survival via expression of Bcl-2 or other antiapoptotic proteins, such as, possibly, Bcl-Xl [250]. However, enforced expression of Bcl-2 was not sufficient to rescue B-cell development and γδ T-cell development [69,248,249]. Here, IL-7R-mediated signals are necessary for the rearrangement of immunoglobulin heavy chain V segments via *Pax*-5 gene activation [251,252] and for V-J recombination of γδ TCR genes via Stat5 [253,254]. Therefore, IL-7R signaling can either lead to the transmission of "trophic" survival signals in the T-cell lineage or "mechanistic" differentiation and proliferation signals in the B and γδ T-cell lineage, respectively. Thus, it was reasonable to search for oligopotent common lymphoid progenitors (CLPs) within the Lin^{-}IL-7Rα^{+} fraction in adult mouse bone marrow. We identified a population of Lin^{-}IL-7Rα^{+}Thy-1^{-}Sca-1^{lo}c-kit^{lo} cells that also express γc, indicating that this population possesses functional IL-7R (Figure 4.1) [248]. In contrast, both LT-HSC and ST-HSC populations are IL-7Rα^{-}. These CLPs possess rapid and potent T, B, and NK cell-restricted differentiation activity in reconstitution assays. In both in vitro and in vivo assays, Lin^{-}IL-7Rα^{+}Thy-1^{-}Sca-1^{lo}c-kit^{lo} cells completely lack myeloid differentiation activity [248]. Also no day 8 and day 12 CFU-S activity could be detected [129,248]. Injection of 1000 CLP could generate $0.6 - 1.1 \times 10^7$ CD3^{+} spleen T cells by 4–6 weeks, and 1.4×10^7 B220^{+} spleen B cells by 2 weeks in vivo. CLP-derived T- and B-cell generation peaks 7–10 days earlier than similar numbers of T and B cells derived from the same number of HSCs [248]. However, in contrast to HSC-derived cells, numbers of CLP-derived T and B cells begin to decline after 4–6 weeks, indicating that this population has no or limited self-renewal activity. Using a two-step assay we demonstrated that CLPs contain clonogenic progenitors for both T and B cells. Single cells were cultured in methylcellulose in the presence of SLF, IL-7, and Flt3 ligand to expand cell numbers, and a portion of the day 3 colonies were picked up and injected directly into the thymus. Those injected into the thymus differentiated into all stages of T-cell development and, in some cases, differentiated into both T and B lineage cells. The further cultured cells formed B-lineage colonies composed of pro-B and pre-B cells [248]. Therefore, the defined CLPs match the criteria for the definition of oligopotent progenitor cells. We have subsequently shown that the purity of CLP is further refined based on its expression of Flk2, whereas the Flk2^{-} fraction of the previously defined CLP contains B-committed cells [255]. Accordingly, CLPs exist downstream of Flk2^{+} ST-HSCs and MPPs in normal hematopoiesis [31,32,256].

Based on their frequency in bone marrow, cycling status, and in vivo T-, NK-, and B-cell generation potential, CLPs theoretically could be a developmental intermediate for most if not all mature lymphoid cells. The commitment of CLP to either the T, B, or dendritic cell lineage may be determined simply by the microenvironment and signals that CLPs encounter. However, whether CLPs are an indispensable stage of T- and B-cell development remains unclear.

Coffman et al. identified the B220 marker that is present on all B-lineage cells [257] and early B-cell progenitors were found to be B220^{+}, CD43^{+}, CD24^{-}BP1/6C3^{-} [157,158]. Hardy and colleagues further subdivided B-cell progenitors into fractions: prepro-B cells (fraction A0, AA4.1^{+}CD4^{lo}B220^{-}HSA^{-}; A1, AA4.1^{+}CD4^{+}B220^{+}HSA^{-}; A2, AA4.1^{+}CD4^{-}B220^{+}HSA^{-}); and pro-B cells (fraction B, B220^{+} CD43^{+}HSA^{+}6C3/BP-1^{-}; C, B220^{+}CD43^{+}HSA^{+}6C3/BP-1^{+}) [258–260] (also reviewed in [261]). The majority of fraction A1 cells are c-kit^{-}, lack myeloid potential, but possess minor T-cell potential that can be detected after intrathymic injection. Pro-B cells are B-lineage committed, rearrange D_H-J_H genes (fraction B), and undergo V-DJ recombination (fraction C). In view of their T- and B-cell readout capacity, the A0 and A1 fractions could contain CLPs, but because different markers were used for their isolation, a direct comparison of data from these populations is not possible. However, a majority of A0 and A1 fraction cells do not express IL-7Rα, but A2 cells do. B-lineage development has subsequently been studied in detail by a variety of groups using different combinations of markers that prevented direct comparison of the data [258,260,262–268]. Subsequently, we performed analyses to clarify these data by incorporating the majority of these described markers and others in our experiments. These studies allowed us to identify a committed B-lineage progenitor downstream of the CLP with the surface phenotype of B220^{+}CD43^{+}AA4.1^{+}Flk2^{+}CD27^{+}IL7Ra^{+}c-kit^{lo}CD24^{-}CD19^{-}CD11c^{-} Ly6c^{-}CD4^{-} [269]. We later found a population of cells in the CLP gates that expresses Ly6D, and these appear to be the earliest committed B-lineage cells in the mouse identified to date [269].

The earliest thymic progenitors (DN1, double negative 1 cells) are CD4^{lo}CD8^{-}CD44^{+}CD25^{-}c-kit^{+} cells [270–273]. Most of these early thymic progenitors are T-cell committed (pro-T cells); however, some cells within this population are capable of differentiating into B, NK, and dendritic cells (DCs), as well as, at a low frequency, myeloid cells [273], but their clonal origin has not been established [272–274]. Whether the earliest thymic progenitor population contains a small number of recently homed CLPs that, within this microenvironment, preferentially differentiate into T cells, or whether CLPs commit to the T-cell lineage while still in bone marrow and successively home to the thymus [275] has been controversial. By reductive isolation of cells with a single marker at a time, we have found that the thymic progenitors in the bone marrow are all of the CLP phenotype [276].

Allman et al. [277] suggest that thymopoiesis is maintained through early thymic progenitors (ETPs) that may develop from bone marrow progenitors more closely related to HSCs and not via a CLP-dependent pathway. This is based on findings that some cells (ETPs) within the DN1 fraction: do not express IL-7Rα at high levels; have some myeloid potential; give rise to T and B cells with kinetics that resemble those of ST-HSCs [32] more closely than that of CLPs; and were present at near-normal frequencies in Ikaros$^{-/-}$

mice while CLPs were not detectable by phenotype. While these data add important information on possible alternative T-cell developmental pathways, they do not assess directly how many ETPs or mature T cells are CLP-derived or whether most thymopoiesis is independent of CLPs. Both MPPs and CLPs injected intravenously give rise to thymocytes, but the MPPs do so with delayed kinetics reflective of their homing to the BM and giving rise to CLPs that then go on to seed the thymus directly. Additionally, thymic myeloid cells were observed to derive from transplanted MPPs and not CLPs, suggesting that these cells are the progeny of myeloid progenitors that also enter the thymus. Further, when Flk2$^+$ CLPs were plated in conditions capable of supporting differentiation into multiple lymphoid and myeloid lineages, single CLPs gave rise to T, B, NK, and DC lineages [276]. Approximately 50% of single CLP clones gave rise to both B- and T-lineage cells in this assay and none gave rise to any macrophages or neutrophils [278]. Taken together, these data confirm the role of CLPs as potent progenitors of both B and T lymphocytes in vivo and in vitro. Also of note, CLPs co-transplanted with HSCs in autologous or allogeneic transplantation models can rescue mice from otherwise lethal cytomegalovirus (mCMV) infections [279], providing additional evidence for the robust *and* functional T and/or NK cell reconstitution capacity of CLPs in vivo.

In humans, evidence for a T/NK bipotential precursor population in the fetal thymus [280] and a terminal deoxynucleotidyl transferase (TdT) positive candidate lymphoid precursor population in CD34$^+$ bone marrow cells has been reported [281]. However, clonal analysis was not carried out. A subpopulation of the CD34$^+$TdT$^+$ cells express the neutral endopeptidase CD10 [282]. Later it was shown that fetal and adult bone marrow Lin$^-$CD34$^+$Thy-1$^-$CD38$^+$CD10$^+$ cells contain clonal progenitors of B, NK, and dendritic cells [283]. As a population, these cells give rise to T cells in the SCID-hu thymus assay but could not generate myeloid progeny. Another report stated that cord blood CD34$^+$CD38$^-$CD7$^+$ cells contain clonal B, NK, and DC precursors; however, T-cell readout was not evaluated [258]. Therefore, both studies suggest but do not formally demonstrate the existence of CLPs in humans. IL-7 signaling may not be essential for normal B-cell development in humans, because B cells can be generated without IL-7 in vitro [284], and disruption of the IL-7R in vivo causes T-cell but not, consistently, B-cell deficiencies [285,286] (reviewed in [282]). Human early lymphoid progenitors, in analogy to mouse CLPs, express IL-7Rα. Indeed, Lin$^-$CD34$^+$CD38$^+$CD10$^+$ cells can be subdivided into a CD10$^+$IL-7Rα$^-$ and a CD10^{lo}IL-7Rα$^+$ fraction, with the latter being highly enriched in clonal B-cell progenitors [287]. It has also been shown that pro-B cells proliferate and differentiate in culture with IL-7 and BM stromal cells, whereas pre-B cells are no longer responsive to IL-7 [288]. It is important to determine whether CD10^{lo}IL-7Rα$^+$ cells or CD10$^+$IL-7Rα$^-$ cells contain both T- and B-cell progenitors and whether thymus seeding cells share some of these phenotypes (for a review of human early thymocyte development see [289]).

Common myeloid progenitor cells and myeloid development

The identification of the CLP in the IL-7Rα-expressing fraction of mouse bone marrow that holds no myeloid differentiation activity [248] suggested that complementary progenitors common to all myeloid cells may exist in the IL-7Rα$^-$ cell fraction. In addition, we had noted that the Sca-1$^-$ subset of Thy-1^{lo}Lin$^-$ cells contained myeloerythroid progenitors [30]. Therefore, to exclude HSCs and CLPs, we searched for myeloid progenitors within the Lin$^-$IL-7Rα$^-$Sca-1$^-$c-kit$^+$ bone marrow fraction. We identified three myeloid progenitor populations [102]: common myeloid progenitor cells (CMPs, FcgR^{lo}CD34$^+$; now known to be Sca-1^{lo}, not Sca-1$^-$ [290]), and their lineal descendants; megakaryocyte/erythrocyte progenitor cells (MEPs, FcgR^{lo}CD34$^-$); and granulocyte/macrophage progenitor cells (GMPs, FcgR^{hi}CD34$^+$).

These three myeloid progenitor subsets likely represent the major pathways for myeloid cell differentiation because they contain the vast majority of myeloid progenitor activity in steady-state bone marrow. CMPs give rise to all myeloid colonies in vitro including CFU-Mix; GMP give rise to CFU-G and CFU-M as well as CFU-GM; and the MEPs give rise to BFU-E (burst-forming unit, erythroid), CFU-Meg, and CFU-MegE, each with high cloning efficiency. We demonstrated that CMPs as a population differentiate in vitro into cells with MEP and GMP phenotypes and functions [102]. Furthermore, the majority of single CMPs generate both GM- and MegE-related progeny. Upon in vivo transfer, the three cell populations give short-term but not long-term readout, corresponding to their in vitro activities, and indicating that they have only limited if any self-renewal activity [129].

MEPs provide radioprotective cells for lethally irradiated mice housed under infection control conditions [129]. Lethally irradiated mice injected with MEPs, CMPs, ST-HSCs, or MPPs show transient donor-derived hematopoiesis sufficient to sustain survival while reconstitution with residual host HSC occurs [29,69,129]. In addition, the majority of day 8 CFU-S activity resides within the MEP population, but is absent from the GMP population [129], supporting previous findings that day 8–9 CFU-Ss are largely erythroid [30,291]. Our data also confirm previous findings that the majority of day 12 CFU-S activity resides not within lineage-committed progenitors but within the more primitive HSC populations, with some activity in CMPs and MEPs [29,30,292]. Neither B- nor T-cell differentiation activity was detectable in either MEPs or GMPs. CMPs could not generate T cells; however, a small number of B-cell progeny were detectable in vitro and in vivo [102]. We also isolated a pure population of megakaryocyte progenitors (MKP) in mice. These Lin$^-$c-kit$^+$Sca-1$^-$CD34$^+$CD9$^+$CD41$^+$ cells are highly efficient at producing megakaryocyte CFC in vitro, micro-megakaryocyte loci in vivo, and donor-derived platelet production in vivo, while they are devoid of erythrogenic activity [293].

The subsequent identification of additional markers has enabled higher resolution delineation of myeloid developmental pathways. First, we and others found that the CMP population, like the CLP, was heterogeneous for Flk2 expression [255,294] and the Flk2$^+$ fraction contained the CMP activity and could give rise to GMPs and MEPs and all myeloerythroid progeny including DCs. Subsequently, the addition of CD150 (Slamf1), CD105 (Enderlin), and CD41 to the analysis revealed further heterogeneity within the myeloid progenitor populations [295]. These markers revealed that the previously defined CMP could be further subdivided into CD150$^+$ and CD150$^-$ fractions, and the MEP can be divided into three subpopulations based on endoglin and CD150 expression. Detailed analyses with these markers led to the identification of isolatable preGM, preMegE, and preCFU-E populations that give appropriate lineage restricted readouts in vitro and in vivo [295]. The current lineage trees from mouse and human HSC are shown in Figure 4.1.

These data are consistent with another study that used a Gata1-GFP reporter to identify a population that refines the CMP phenotype or precedes it in the developmental scheme [290]. Specifically, this population is Lin$^-$Kit$^+$Sca^{int}Flk2$^-$ Gata1^{lo} and gives rise in vivo to all myeloid lineages, but has very low lymphoid readout. Using a PU.1 reporter, this study also identified a GLMP that could give rise to lymphocytic and myeloid lineage cells but not platelets. These results are similar to those from Adolfsson et al. which indicated that MPPs that express the highest levels of Flk2 have lost platelet-forming ability [296]. This is also consistent with data suggesting that PU.1 represses MegE development [297].

Alternative developmental pathways

There are several recent in vivo studies as well as in vitro data that suggest that myeloid versus lymphoid differentiation may not always be the first lineage determination made during hematopoietic development and either bipotent B-cell/myeloid, or T-cell/myeloid progenitors, or both may exist. In support of a B/macrophage progenitor, it was demonstrated that several B-cell lines can be modified to produce cells with features of macrophages by in vitro manipulations [298–300]. Importantly, transfection of v-raf into B-cell lines established from Eμ-*myc* transgenic mice could convert them into macrophages that maintained the identical rearrangement of an IgH gene [299]. This observation suggests that latent developmental potentials that are not accessible under normal conditions may be regained through genetic alteration. Indeed, in the first experimental reprogramming of an in vivo cell, we have shown that CLPs, which under normal conditions never generate myeloid readout, produced granulocytes and macrophages after they were genetically engineered to express the human IL-2 receptor β chain (hIL-2Rβ) or the granulocyte–macrophage colony-stimulating factor receptor (GM-CSFR) and were stimulated with the cognate ligands [301]. This was blocked by enforced expression of Pax-5 [302].

Also in vitro, single FL cells could give rise to both B/myeloid and T/myeloid progeny [224,303,304]. In these experiments using a FTOC system in the presence of 60% O_2 for single cell readout, Kawamoto et al. [304] detected B/T/myeloid, B/myeloid, T/myeloid, but never T/B bipotent progenitors from FL cells populations [304]. However, in these high O_2 concentration cultures, only ~5% of single $Lin^-Sca\text{-}1^+c\text{-}kit^+$ HSCs gave rise to multilineage (T/B/myeloid) outcomes, suggesting that this system is not reproducible enough to demonstrate all differentiation capacities of HSCs. Also, differentiation into T/myeloid or B/myeloid lineages might simply occur because of the "random" commitment of HSCs in these culture conditions. Alternatively, T/B committed bipotent progenitors might not be contained in the $Lin^-Sca\text{-}1^+c\text{-}kit^+$ population but only in the $Lin^-Sca\text{-}1^{lo}c\text{-}kit^{lo}$ CLP fraction [248,305]. Bipotent B/macrophage progenitors were also described at a very low frequency (~0.02%) in adult hematopoiesis in vitro [306], supporting the hypothesis that a B/macrophage developmental line might be conserved beyond fetal hematopoiesis.

As described earlier, additional data also suggest that HSCs and progenitors circulate through the blood and reside in the tissues before returning to the blood via the lymphatics [147]. Further, these cells were shown to differentiate in the tissue directly into dendritic, myeloid, and $B220^+$ cells. This result together with results showing that HSCs respond to a reduced hematocrit [307], in vitro data providing evidence for direct differentiation to megakaryocyte development [70], and studies suggesting oligo and bipotent progenitors, suggest that HSCs percolate through the tissues as a means of directly assessing specific hematopoietic and immune demands. It is reasonable to hypothesize that these cells reflect the responsiveness of the hematopoietic system and indicate that steady-state hematopoiesis, when demand for each lineage is constant, is distinct from hematopoiesis during infection or blood loss, when there is a specific need for an increase in certain lineages. Being able to shut down production of lineages not in demand would also be a means of conserving resources such that white blood cells are not generated at the expense of red blood cells (RBCs) during anemia and, conversely, RBCs and platelets are not generated at the expense of innate or specific immune cells when these are in demand.

Human myeloid progenitors

As in the case of CLPs, multiple studies suggested the existence of human oligopotent myeloid progenitors [308–312]. We identified human bone marrow and cord blood cell populations that are counterparts of the mouse CMPs, GMPs, and MEPs [287]. They are negative for multiple mature lineage markers (including early lymphoid markers that might define human CLPs as CD7, CD10, or IL-7Rα) and all are $CD34^+CD38^+$. They are distinguished by the expression of CD45RA, an isoform of the CD45 cell-surface tyrosine phosphatase that can negatively regulate at least some classes of cytokine receptor signaling [313], and IL-3Rα, a receptor that, upon activation, supports proliferation and differentiation of primitive progenitors [70,314,315]. $CD45RA^-IL\text{-}3R\alpha^{lo}$ (CMPs), $CD45RA^+IL\text{-}3R\alpha^{lo}$ (GMPs), and $CD45RA^-IL\text{-}3R\alpha^-$ (MEPs) show high myeloid cloning efficacy but low long-term (stromal hematopoietic) culture-initiating cell (LTC-IC) capacity, indicating that they do not self-renew. Although FcγR II-III (CD16/CD32) expression distinguishes mouse CMPs and GMPs, it was not detectable on any of the human myeloid progenitor populations; and all human clonal myeloid progenitors express CD34 while mouse MEPs are $CD34^-$ [102]. Interestingly, in mouse myeloid progenitors, IL-3Rα as well as CD45RA expression were both negative to low in MEPs, intermediate in CMPs, and positive in GMPs, without providing sufficient discrimination to clearly set a cut-off level between the different cellular fractions. As with the mouse myeloid progenitors, CMPs give rise to MEPs and GMPs in vitro, and a significant proportion of CMPs have clonal granulocyte/macrophage and megakaryocyte/erythrocyte readout potential. We did not test T-cell differentiation ability; however, no in vitro B or NK cell readout could be detected. However, some B cells might develop from large numbers of transplanted CMPs. As in the case of mouse CMPs, it is important to clarify whether the CMP population contains oligopotent B/myeloid progenitors, or monopotent B-cell progenitors that share CMP phenotypes but do not read out in our in vitro assay, or whether in vivo B-cell readout resulted from small numbers of contaminating B-cell progenitors in the large number of transplanted cells (see later).

Lineage commitment in fetal hematopoiesis

While fetal liver (FL) HSCs show major similarities to adult HSCs, some phenotypic and functional differences exist [186,316–318]. Remarkably, FL-HSCs possess some cell fate potentials such as the generation of $V\gamma3^+$ and $V\gamma4^+$ T cells [190] and B-1a lymphocytes [319,320] that are not detectable in adult HSCs. Therefore, it was important to determine the phenotype and developmental capacities of fetal liver CLP and CMP. We identified FL-CLPs ($Lin^-IL\text{-}7R\alpha^+B220^{-/lo}Sca\text{-}1^{lo}c\text{-}kit^{lo}$) [305], and the myeloid progenitors FL-CMPs ($Lin^-IL\text{-}7R\alpha^-Sca\text{-}1^-c\text{-}kit^+AA4.1^-FcgR^{lo}CD34^+$), FL-GMPs ($Lin^-IL\text{-}7R\alpha^-Sca\text{-}1^-c\text{-}kit^+AA4.1^-FcgR^{hi}CD34^+$), and FL-MEPs ($Lin^-IL\text{-}7R\alpha^-Sca\text{-}1^-c\text{-}kit^+AA4.1^-FcgR^{lo}CD34^-$) [321] that show high similarities to their adult counterparts. However, some significant differences in proliferative potential colony-forming activity and lineage differentiation capacities exist. Of special note, FL-CLPs generate $CD45^+CD4^+CD3^-LTb^+$ cells that are initiators of lymph node and Peyer's patch formation

[322–325]; these represent an innate lymphoid cell unrelated to NK cells. About 5% of these IL-7R$^+$ FL-CLPs differentiated into macrophages and B cells, at least in vitro. Interestingly, the FL-CLPs fail to express Pax-5, a suppressor of macrophage development [323] while adult marrow CLPs that lack myeloid potential are Pax-5$^+$ [305]. Conversely, although FL-CMP and downstream FL-MEPs or FL-GMPs do not give rise to T cells, FL-CMPs possess some in vitro and in vivo B-cell potential. A close relation between B-cell and macrophage development for adult and fetal hematopoiesis was suggested before (see later). Therefore, during commitment to the lymphoid or myeloid lineage in FL hematopoiesis, the developmental capacity for macrophages and B cells might be the last to be lost in commitment to either the lymphoid or myeloid lineage.

DC development

DCs were initially defined as bone marrow-derived non-macrophage leukocyte populations with high antigen presentation capacities and the ability to prime naïve T cells [326–328]. Multiple DC subpopulations that differ in tissue distribution, surface-marker expression and functional capacities have been described in humans and mice (reviewed in [329,330] and Chapter 17), and additional subpopulations continue to be identified. From an evolutionary point of view, DCs may belong to the myeloid and lymphoid lineage because they link the innate and adaptive immune responses. Based on current data, two opposing models of DC ontogeny can be suggested: either the mature DC subpopulation is determined at the level of an early hematopoietic progenitor or, alternatively, immature DCs retain the capacity to mature to distinct DC subpopulations in response to different environmental instructions.

In mice, two major DC subpopulations are distinguishable by their expression of the CD8α chain [331]. Early intrathymic progenitors (TPs) (CD4^{lo}CD44$^+$CD25$^-$c-kit$^+$) and thymic pro-T cells (CD44$^+$CD25$^+$c-kit$^+$) reportedly contain precursors able to differentiate into CD8α$^+$ DCs in vivo [274,332]. Therefore, and because the majority of thymic DCs and only a minority of secondary lymphoid organ DCs express CD8α$^+$, the CD8α$^+$ DCs had been considered to be related to the T-lymphoid lineage and were therefore termed "lymphoid DCs" in contrast to the CD8a$^-$ "myeloid DCs." This model seemed to be supported, but not directly demonstrated, in mice deficient for the transcription factors RelB [333], PU.1 [334], and Ikaros [335] that lack only CD8a$^-$ DC. However, other mutants, such as c-*kit*$^{-/-}$, γc$^{-/-}$ [336], and Notch-1$^{-/-}$ [337] mice, showed a developmental dissociation of CD8α$^+$ DC and T cells. We and others therefore tested DC developmental potentials in adult and fetal lymphoid and myeloid committed progenitors. Surprisingly, CD8α$^+$ and CD8α$^-$ DCs were produced both by highly purified CLPs and CMPs with similar efficacy on a per cell basis, therefore disproving the concept of CD8α$^+$ "lymphoid"- and CD8α$^-$ "myeloid"-derived DCs in mice [305,337–340]. Furthermore, beyond CLPs and CMPs, DC developmental potential is conserved in the lymphoid lineage in pro-T cells and in the myeloid lineage in GMPs, but it is lost once B-cell or megakaryocyte/erythrocyte commitment occurs [337,338].

In contrast to mice DCs or their precursors, which are usually isolated from the lymphoid organs or bone marrow, human DCs and their precursors have usually been isolated from peripheral blood and only in rare cases from blood-forming organs, making direct comparisons difficult (for a review see [330]). However, DCs could be generated from total CD34$^+$ progenitor populations, lymphoid-restricted progenitor populations, and peripheral blood monocytes, suggesting that DC developmental potential in human is analogous to that in mouse and is conserved in myeloid and lymphoid-restricted lineages [283,340–345]. An immediate DC precursor population that, upon stimulation, can produce large amounts of interferon-α, displays a set of distinct pattern recognition receptors and can mature into DCs in vitro, was identified in humans [346–349] and later in mice [350–352]. This DC subpopulation was termed plasmacytoid DCs, DC2 and interferon-α-producing cells [329]. These cells can derive from both myeloid and lymphoid progenitors (reviewed in [81]) but are predominantly of myeloid origin [353].

In summary, DCs develop along a lymphoid and myeloid pathway in vitro and in vivo. By using simple assays – such as immunophenotyping, or functional readout as mixed lymphocyte reaction and cytokine production – we did not detect differences in lymphoid precursor- and myeloid precursor-derived CD8α$^+$ DC fraction DCs [338]. This is an unexpected finding, because it suggests developmental redundancy for DCs. More likely is that CLP- versus CMP-derived DCs have functionally distinct roles. Of note, DC developmental capacities in CLPs and pro-T cells correlate with their latent myeloid developmental potential that can be "rescued" by artificial introduction and activation of the IL-2β or GM-CSF receptor [301,354]. It would therefore be important to characterize the signals that are involved in retaining DC developmental capacities in the otherwise exclusively lymphoid or myeloid committed progenitor cells. Activation of the Flt3 tyrosine kinase could be one of these signals [255].

Gene expression profiles of HSCs and their oligolineage progenitors: Gene Expression Commons

Several powerful technologies have allowed the characterization of transcripts expressed in defined cells, populations of cells, tissues, and organs. These technical advances allow for reductionist approaches to understand the complexity of RNA transcripts found in these cells or tissues, and how the transcriptional profile changes upon differentiation, self-renewal, or other functional events. One of the most powerful technologies is microarray analysis, wherein the expression profile of transcripts for a high fraction of all known genes in the species can be ascertained for purified cell populations. Several groups have performed microarray expression profiling of hematopoietic stem and progenitors cells from fetal, adult, and aged mice [74,75,78,79,256,295,355–357]. These studies have identified several genes that have been subsequently validated as important for HSC function, such as *BMI1* [78], or useful for HSC purification, such as *Slamf1* [75,355]. Gene subtractions or other differential expression techniques have revealed a subset of genes that appear to be expressed in HSCs, but not broadly elsewhere. In fact, some genes have been found that are expressed in HSCs and neurosphere cultures (highly enriched for CNS stem cells) [130], or HSCs and ES cells, or all three [130,358].

We have recently published a user-friendly set of microarrays from all known mouse and human hematopoietic subsets, called Gene Expression Commons [104]. Shown in Figure 4.6 are four examples of the utility of this absolute comparison of the array data for any particular cell type versus the entire RNA on the array. In the examples shown, four genes (*c-Mpl*, *EpoR*, *IL-7R*α, and *c-EBP*α) were entered into the database, and the absolute comparison of each hematopoietic subset is shown.

These gene expression arrays cannot detect important events that are essentially post-translational, for example the phosphorylation

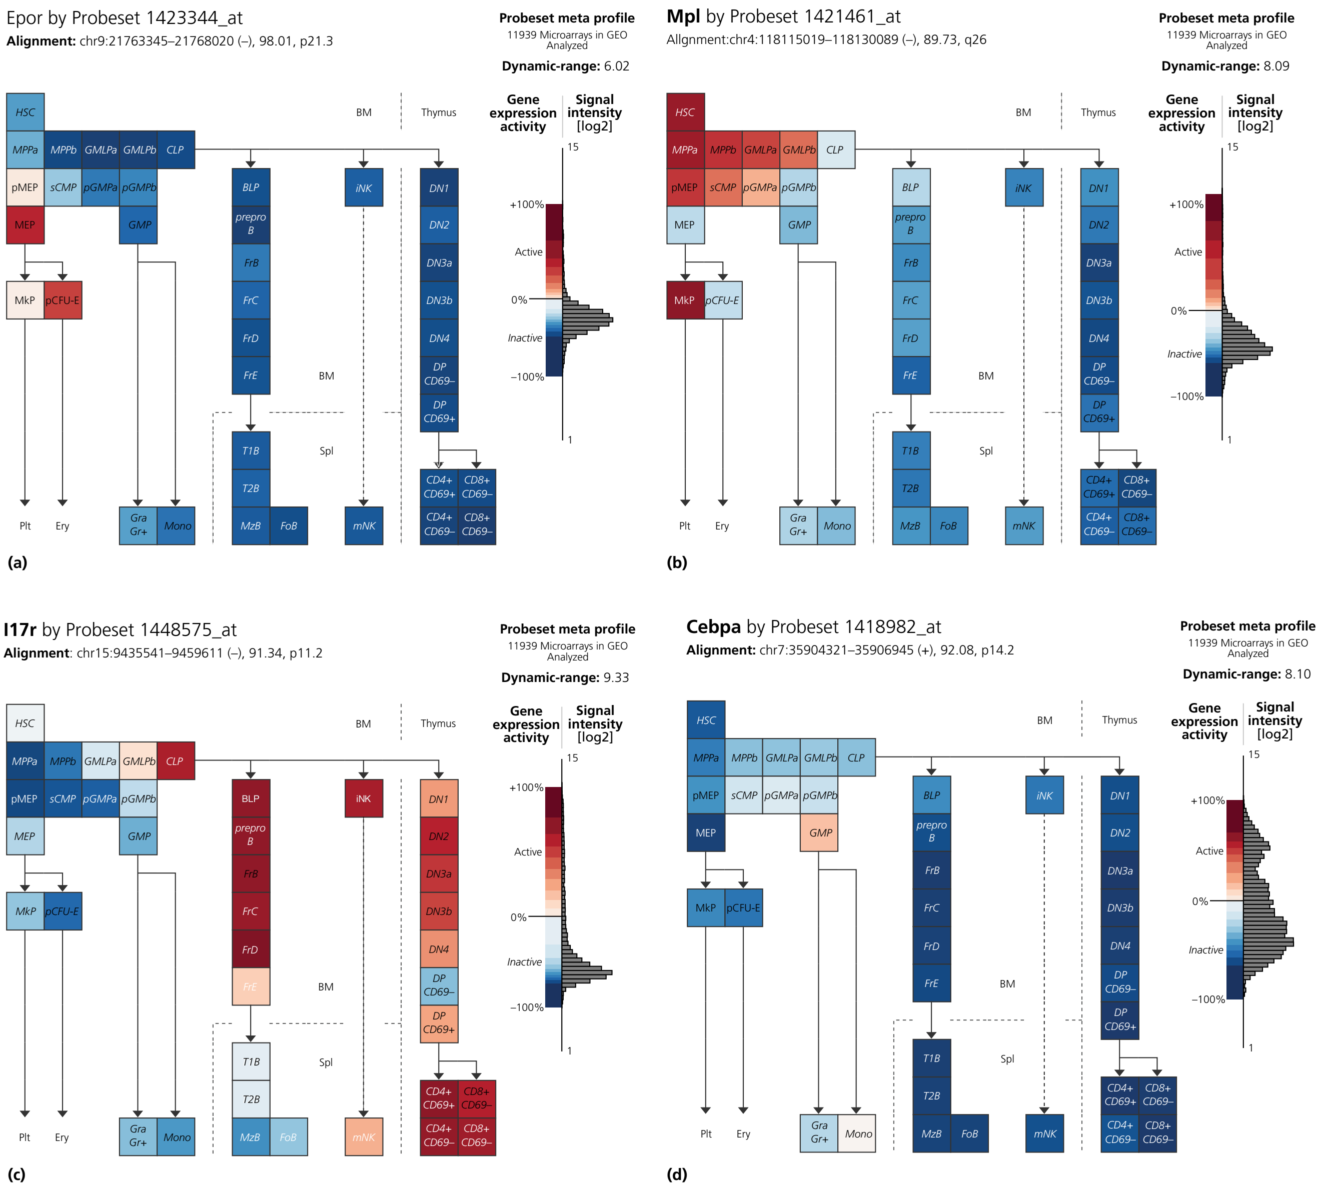

Figure 4.6 Images from Gene Expression Commons (https://gexc.stanford.edu/) showing absolute comparison of the array data for particular genes (*EpoR*, *c-Mpl*, *IL-7Rα*, and *c-Ebpα*). Raw microarray data are individually normalized against a large-scale common reference, then mapped onto each probe-set metaprofile. This strategy enables profiling of absolute expression levels of all genes on the microarray. (For a color version of this figure, please see the color plate section.)

and dephosphorylation of proteins in signal transduction pathways, or the changes in subcellular locations of proteins, such as β-catenin, under conditions when they are held within the degradation complex, or attached to the cytoplasmic face of cadherins, or allowed to be free in the cytoplasm and appear in the nucleus [112]. Most of the oligolineage progenitors downstream of mouse HSCs [102,248] and human HSCs [41,283,287,340] have been isolated to homogeneity, and in some instances a comparison of their gene expression profiles reveals important clues as to genes responsible for particular commitments to differentiated fates [130,357] (see later). The reductionist approach to cataloging genes in this way will likely reveal many new clues about stem cell behaviors, but a similar cataloging of cellular proteins (proteomics) will be required to reveal cell protein modifications that may help identify important pathways in stem cell behaviors.

Promiscuous expression of multiple myeloid or lymphoid genes in hematopoietic branchpoints

Prospectively purified LT-HSCs, oligopotent progenitors, and lineage-committed progenitors have been used for a definitive sampling of the transcriptional profiles of cells at these particular stages of physiologic hematopoiesis. The expression patterns of lineage-affiliated genes in each stage of hematopoiesis are largely consistent with their known functions. Semiquantitative RT-PCR assays targeted for each purified population provided the following results. *SCL* (stem cell leukemia) [359,360] is expressed in HSCs and all myeloid progenitors. *GATA-2* [361] and *c-Mpl* are expressed in HSCs, CMPs, and MEPs, but not in GMPs [74,102,103]. Other megakaryocyte/erythroid (MegE)-related genes such as *NF-E2* [360], *GATA-1* [362,363], and the erythropoietin receptor are expressed in CMPs and MEPs but not in GMPs, and their expression levels are highest in MEPs [103,357]. Granulocyte-affiliated transcription factor, C/EBPα [364] is expressed in HSCs, CMPs, and GMPs, but not in MEPs, and its expression level is highest in GMPs [103,357]. All of these genes are expressed in CMPs, but not in CLPs or other late lymphoid progenitors, suggesting potential roles for each in myeloid-specific cell fate determinations. In contrast, the lymphoid-related transcription factor Aiolos [365] is not expressed in any myeloid progenitors, nor in HSCs. Ikaros, an Aiolos partner nuclear factor, thought initially to be a lymphoid-specific transcription factor [212,366], is expressed in HSCs and all stages of hematopoiesis [367]. Aiolos first appears at the CLP stage, and is highest in T- and B-cell progenitors [102,103]. Lymphoid-related GATA-3 [368] and Pax-5 [369] are expressed at a low level in adult marrow CLPs but not in myeloid progenitors and fetal liver CLPs [102,305].

These data provide a clearer view of gene expression regulation in hematopoietic development. First, the expression of many myeloid and lymphoid genes is mutually exclusive in each pathway. Second, CMPs express both MegE and GM-affiliated genes, and CLPs express both T- and B-lymphoid genes, although CMPs and CLPs have not committed to myeloid and lymphoid sublineages, respectively [102,103]. These data are consistent both with the priming hypothesis [370] and a model wherein chromatin is open prior to commitment, but the transcripts from that open chromatin are not critical for maturation [103].

The view of myeloid or lymphoid promiscuity has been significantly extended by using an oligonucleotide microarray analysis targeted for purified CMPs and CLPs. Genome-wide profiling by using microarray methods revealed that CMPs and CLPs co-express a vast majority of GM and MegE-affiliated genes, and T, B, and NK lymphoid genes, respectively [74,357]. Furthermore, co-expression of both GM and MegE-related genes in CMPs and of both T and B lymphoid genes in CLPs have been formally demonstrated at the level of single cells [74]. RT-PCR analysis targeted for single cells has been used to determine that CMPs co-express MegE-related β-globin, EpoR, NF-E2, and GM-related MPO, G-CSFR, and PU.1, while CLPs co-express B-cell-related l5 and/or Pax-5 and T-cell-related CD3d and/or GATA-3 [103]. These results indicate that the expression of lineage-related genes can precede commitment, and suggest that the "promiscuous" expression of multiple lineage-related genes may allow a flexibility of commitment at these oligopotent stages: for differentiation towards T- and B-cell lineages in CLPs, and towards GM and MegE lineages in CMPs.

It is still unclear whether the primary mechanism of hematopoietic commitment could be operated first by opening chromatin at programmed sites, or whether the "priming" seen in promiscuous transcription patterns results from the presence of open chromatin and transcription factors that can form "sterile" transcripts. Nonetheless, in priming stages, multiple differentiation programs may collaborate or compete with each other until one becomes dominant. These programs should include cross-talk among transcription factors or transcriptional complexes, because transcription factor activity can be potentiated [371] or suppressed [372,373] by interaction with other transcription factors. Changes in levels of key transcription factors [374,375] may also be critical for the lineage decision. Cross-talk between different cytokine signals may also be important, as single progenitors co-express multiple cytokine receptors. Furthermore, fluctuations of gene expression of multiple differentiation programs in progenitors may lead to different outcomes depending on the microenvironment the cell inhabits. In this context, both intrinsic and extrinsic factors could play a part in lineage determination. However, data comparing HSCs from young and old mice show an intrinsic change in their differentiation potential with decreasing lymphoid potential with age, even when transplanted into a young mouse [77]. These data suggest that at least some portion of lineage determination is independent of the environment or that aging HSCs irreversibly lose responsiveness to signals provided by it.

One way to view the hematopoietic system is to assume that at or around the stage of yolk sac hematopoiesis, a pool of HSCs are created that are the only source of hematopoiesis for life. Each early HSC then is a clonogenic precursor of other HSCs, which self-renew, and their progeny, which do not. Over time and perhaps with a cell division counting developmental clock, the clones begin to diversify in terms of responsive potential; these intrinsic epigenetic and rarely genetic changes prime the clones for their responsiveness to normal cues, such as diffusible or membrane-bound factors, or to pathologic cues, such as bacterial endotoxins. At any given point, the clones that are present represent clonal competitions up to that point. In this way intrinsic programs can select certain clones over others, but within an inbred colony of pretty clean mice the clones chosen tend to be consistent, mouse-to-mouse. As we have discussed, this model would have to account for the clonal hematopoiesis model shown in Figure 4.5. We later discuss changes that not only enable clonal selection but are also proto-oncogenic in nature, so that the long process of preleukemic clonal progression is initiated and spread through the HSC clones.

Downregulation of genes irrelevant to committed lineages as a critical mechanism of lineage restriction

According to the "priming" model, commitment could be dependent on two independent molecular events: upregulation of differentiation programs related to selected lineages and the transcriptional abrogation of master control genes in the unselected lineages. A striking example is Pax-5, a key molecule for restriction to B-cell lineage [369]. In normal hematopoiesis, Pax-5 expression initiates at the CLP stage, and is upregulated in pro-B cells, but undetectable in pro-T cells or myeloid cells. Expression of Pax-5 in pro-B cells is important not to differentiate into other lineage cells, because pro-B cells from Pax-5-deficient mice (Pax-5$^{-/-}$ pro-B cells) can differentiate into T cells, NK cells, granulocytes, macrophages, and osteoclasts as well as B cells [369]. Pax-5$^{-/-}$ pro-B cells rearrange the D–J locus of IgH genes and express other pro-B related genes. Thus, even after a set of B lineage-associated genes begins to be transcribed, differentiation programs for other lineages are still accessible. Conversely, enforced Pax-5 expression in myeloid progenitors suppresses myeloid development, presumably blocking signals from myelomonocytic cytokine receptors such as G-CSFR and GM-CSFR [376].

Similarly, enforced expression of PU.1 in pro-T cells can block T-cell differentiation [377]. Ectopic GATA-1 expression in GMPs also inhibits differentiation into granulocyte/monocyte lineages, but induces transdifferentiation into megakaryocytes and erythrocytes [378]. A similar phenomenon is observed in ectopic cytokine receptors. Ectopic expression of IL-2Rβ or GM-CSFR in CLPs can deliver signals that redirect cells to myelomonocytic differentiation [301]. Further characterization of this latent myeloid potential revealed that CEBPα is upregulated in response to the ectopic IL-2 signal and leads to GM-CSFR expression and further myeloid differentiation [379]. This study also revealed that enforced expression of CEBPα in CLP is itself sufficient to induce the myeloid outcome and conversely, enforced Pax-5 expression blocks the myeloid differentiation induced from IL-2Rβ. Similarly, Laiosa et al. showed that committed T cell progenitors could be induced to develop into macrophages or dendritic cells by enforced expression of CEBPα or PU.1, respectively. These data suggest that committed T cell progenitors are also susceptible to the lineage instructive effects of myeloid transcription factors, but that T lineage development occurs by the normal role of Notch signaling downregulating CEBPα and PU.1 in multilineage precursors.

These data indicate that termination of lineage-related gene expression is equally important for completion of lineage commitment. First, in committed progenitors, abrogated differentiation programs for unselected lineages are not totally erased immediately after commitment but could be reactivated by "instructive" signals mediated by ectopic cytokine receptors and transcription factors. For example, GMPs may be restricted to GM lineages simply because GATA-1 is downregulated, and CLPs are likely lymphoid-restricted because they downregulate myeloid cytokine receptors. Second, differentiation programs into committed lineages can be operated on condition that transcription factors for unselected lineages are downregulated, as Pax-5 and PU.1 inhibit myeloid and T-cell differentiation programs, respectively. Thus, a hierarchy of transcription factors and cytokine receptors organized at the epigenetic level is critical to maintain hematopoietic homeostasis.

Changes in chromatin structure, allowing access for RNA polymerase to initiate transcription, is essential for genetic programs to be transcribed [380,381]. The activation of chromatin structure can occur prior to significant expression of genes [382]. It has been hypothesized that a wide-open chromatin structure is maintained in early hematopoietic progenitors, enabling multilineage-affiliated programs to be accessible [383]. This phenomenon of open chromatin in early hematopoietic progenitors could be the mechanism by which lineage priming occurs in stem or progenitor cells prior to their lineage determination [130,371,383,384].

Standard methods for studying chromatin structure require large numbers of cells. This requirement has made application of these methods to stem cell biology difficult, but we and others have made technical advances allowing chromatin immunoprecipitation on rare cells [385–387]. This technique can be used to determine whether the epigenetic marks in control regions of lineage-directing genes are modulated during hematopoiesis. Specifically, we analyzed histone modifications and DNA methylation patterns within the regulatory regions of erythroid (*Gata-1* and β-*globin*), myeloid (*c-fms*), and lymphoid lineage-affiliated genes (*Gata-3* and *Ptcr*α) in 50,000 prospectively purified stem and progenitor cells. By performing bisulfite sequencing analysis, we found that methylated H3K4 and AcH3 and unmethylated CpG dinucleotides localized at defined regulatory regions of these lineage-affiliated genes in HSCs. These histone modifications are epigenetic markers of active transcription and either accumulated or were replaced by increased DNA methylation and H3K27 trimethylation in committed progenitors, consistent with the pattern of gene expression. We also observed bivalent domains at lymphoid-affiliated genes in HSCs and downstream transit-amplifying progenitors. Bivalent domains described by Bernstein et al. contain both activating and silencing histone modifications [388] and are associated with genes such as transcription factors that are expressed at low levels and affect developmental decisions. These data support the role of epigenetic modifications as being reflective of HSC multipotency and suggest that the remodeling of chromatin is an important mechanism of driving gene expression changes associated with developmental decisions.

Transplantation of HSCs in mouse and human

It is fair to say that the field of bone marrow transplantation, now more accurately called hematopoietic cell transplantation (HCT), has provided one of the most striking medical advances in our lifetime and, similarly, the desire to understand cells involved in such transplants has opened the field of stem cell biology, first to HSCs, but then to other tissue-specific stem cells. It is important at the outset, however, to make sure that the scientific and clinical community uses the appropriate nomenclature for the type of transplant used, as misconceptions regarding the cell type transplanted lead to misconceptions about the scientific or clinical results [389,390]. Thus, the transplantation of complex mixtures of hematopoietic cells in bone marrow or mobilized peripheral blood is not the same as transplantation of purified HSCs.

Clinical HCTs have been used for a variety of purposes, but the primary use is to regenerate hematopoietic tissues in a cancer patient who has received otherwise lethal doses of a high-dose regimen of chemoradiotherapy [391,392]. Other uses have been the correction of inherited or acquired hematopoietic cell defects and dysplasias; in animals, the induction of transplantation tolerance to other cells tissues or organs co-transplanted from the donor of HSCs or hematopoietic cells; and the reversal of autoimmune disease [393] (see Chapter 18).

Whether purified HSC transplantation could replace HCT was not clear, as it was unknown whether a rapid and sustained regeneration of a particular hematopoietic outcome could be accomplished with the primitive HSCs alone, without having oligolineage progenitors in the transplant. Several experiments demonstrated in mice and humans that HSCs are the principal cells that are functional in the transplant setting, and that by varying cell dose one could achieve both rapid and sustained regeneration of hematopoietic tissues [394]. Prospective isolation of HSCs with multiple markers allows the possibility that grafts would consist solely of HSCs, and of no other contaminating cells. There are two important advantages, at least theoretically, to the transplantation of HSCs rather than HCT: removal of cancer cells and removal of T cells. Autologous HCT in cancer patients can be accompanied by transplantation of the contaminating cancer cells; in some diseases, such as stage IV breast cancer and many lymphomas, about 50% of the hematopoietic cell populations to be transplanted are contaminated with cancer cells [395–397]. In patients with multiple myeloma, contamination of the graft is the rule and not the exception [398]. Therefore, it was important to test whether positive selection of HSCs would effectively eliminate or purge cancer cells from the transplant.

Deliberate spiking of MPB with cell lines representing human breast cancer, human non-Hodgkin lymphoma (NHL) and human myeloma was performed, and four methods of HCT/HSC isolation were carried out to determine the full reduction of contaminating cancer cells. Two independent methods to identify breast cancer cells were used: microscopy to detect cells carrying breast cell cytokeratins, and a flow cytometry-based method. Myeloma and B-cell lymphoma representative cells were detected by a PCR specific for the immunoglobin heavy chain rearrangements in these B lineage cells. All three techniques have a sensitivity of between 10^{-5} and 10^{-6}.

Over 10^5-fold reductions of contaminating cancer cells were accomplished with the multiparameter cell sorting of $CD34^+Thy^+$ cells from MPB, whereas techniques based on CD34 alone were at least two to three orders of magnitude less efficient (Figure 4.7). The time to reach engraftment with purified HSCs (measured by absolute neutrophil count (ANC) >500 and platelets >20,000/mL of

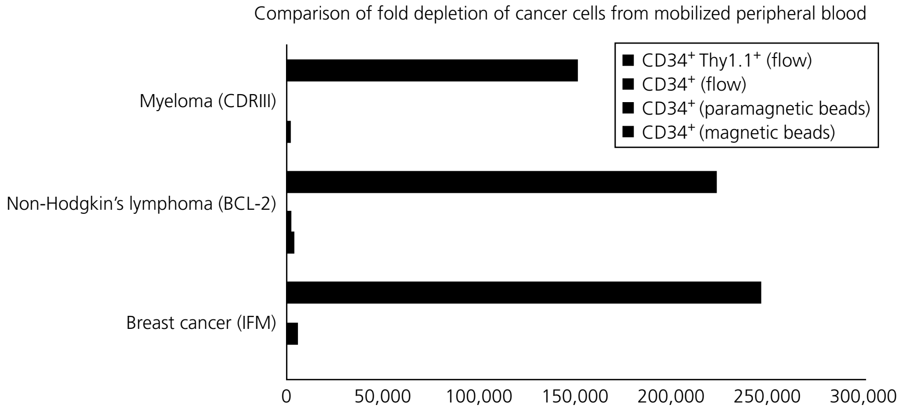

Figure 4.7 Comparison between CD34 only and CD34$^+$ Thy-1 isolation of human stem and progenitor cells in terms of fold depletion of human cancer cells. Mobilized peripheral blood (1.6×10^{10}) was spiked with 1.2×10^8 cancer cells (T47D breast cancer, SU DHL 6 non-Hodgkin lymphoma (NHL) cells, or RPMI-LAV myeloma cells) prior to cell sorting. The CD34$^+$ Thy-1 cells were flow sorted with a modified high-flow cytometer, as were the first CD34 flow sort test. Breast cancer cells were analyzed by immunofluorescence microscopy for cytokeratin, the NHL by Igh-BCL-2 real-time polymerase chain reaction (PCR), and the myeloma by CDR III real-time PCR. The data are represented as fold reduction of cancer cells from the sorted CD34 or CD34$^+$ Thy-1 cells. (E. Hanania, unpublished data.)

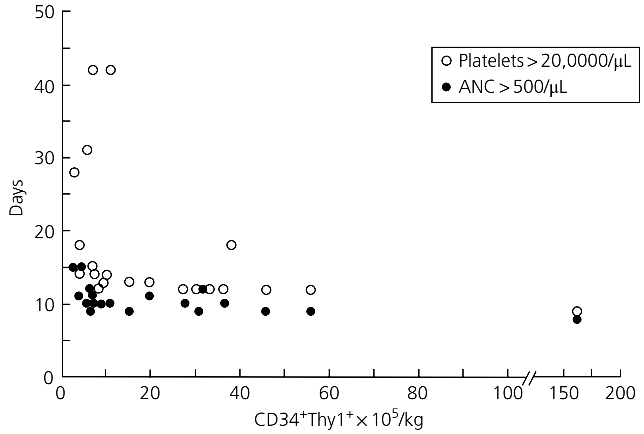

Figure 4.8 Transplantation of highly purified human hematopoietic stem cells (HSCs) in patients with metastatic breast cancer. Shown are the times to engraftment of neutrophils (absolute neutrophil count (ANC > 500/mL)) following transplantation with purified CD34$^+$ Thy1$^-$1$^+$ hematopoietic stem cells. blood [395,396,399]) (Figure 4.8), is very similar to the times obtained when unmanipulated MPB is used as the HCT transplant, and similar to the dose–response observed for mouse HSCs in syngeneic transplants [394]. Even in acute myeloid leukemia (AML), HSCs can be separated from leukemic stem cells by surface markers [400]. We have shown that cancer-free MPB CD34$^+$90$^+$-enriched HSCs from women with metastatic breast cancer engraft rapidly in autologous transplantation following high-dose chemotherapy. About 15 years after transplantation, the overall survival rate was 33% in patients who received cancer-free HSCs but only 9% in a retrospective cohort of patients who received unpurified MPB [401] (Figure 4.9). Because these groups were not prospectively randomized, a larger trial with stage IV or other breast cancer patients with aggressive phenotype cancers or circulating cancer cells should be performed. Also, the stage is set to test whether autologous transplantation of cancer-depleted HSCs from patients with non-Hodgkin lymphoma or multiple myeloma will lead to clinical benefits when compared to transplantation of cancer-containing unmanipulated hematopoietic grafts.

Allogeneic hematopoietic cell transplants have been plagued from the beginning by the appearance of graft-versus-host disease (GVHD) as a result of T cells in the graft [402]. Mice receiving allogeneic HSCs have little or no contaminating T cells, and never develop GVHD [394,403]. Dose–response comparisons of purified HSC transplants in syngeneic, in matched unrelated donor (URD) allogeneic, and in fully allogeneic circumstances have been carried out and, for the most part, doses of HSCs sufficient to allow rapid and sustained engraftment can be achieved without contaminating T cells (Figure 4.10) [403] (also see Chapter 18). However, the number of HSCs required for engraftment can be 10 times higher in the allogeneic than in the syngeneic setting (Figure 4.10) [394].

Graft engineering

One can achieve nearly equal levels of engraftment at the same HSC dose with syngeneic and allogeneic models if the allogeneic hosts are preconditioned with high-dose conditioning regimens that include either facilitator cells (FCs) [404–406] from the donor or monoclonal antibodies that eliminate NK- and T-cell populations [403,407]. High-dose conditioning alone results in donor B cell and myeloid regeneration from the donor alone [403–407] but persistent donor and host T-cell chimerism requires elimination of the host residual T and NK cells with FC or antibodies.

There are two kinds of FCs found in mouse bone marrow and lymphoid tissues: classic CD8α$^+$TCR$^+$CD3$^+$ T cells and CD8α$^+$TCR$^-$ CD3$^-$ FCs [404–406]. The immunocompetent CD8α$^+$TCR$^+$ T cells have some capacity to elicit GVHD disease, and so there is great interest in understanding the nature and function of CD8α$^+$ TCR$^-$CD3$^-$ FCs [404]. There are two other kinds of cells that share this phenotype: CD8α positive immature DCs and veto cells [404,408,409]. We have proposed that all three cell types are in fact a single cell class, and only the assays give the impression that they are different lymphoid cell subsets [404]. This view is strengthened by the findings of Steinman et al. [410] that CD8α$^+$ DCs that do not have active or appropriate co-stimulation can in fact lead to the inactivation or disappearance of T cells (and, we propose, NK cells)

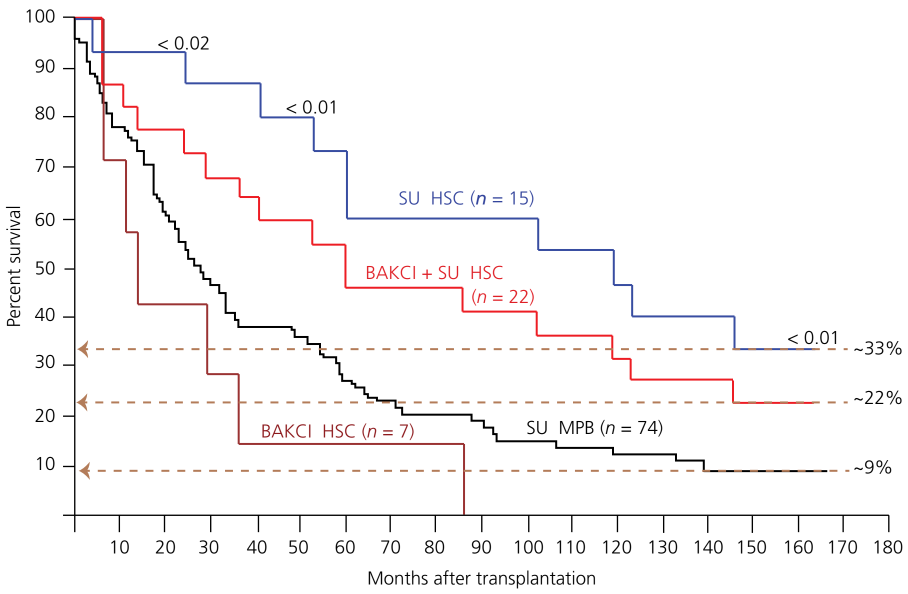

Figure 4.9 Results of several contemporary phase I/II clinical trials of autologous hematopoietic cell transplant rescue in patients with stage IV breast cancer following high-dose chemotherapy (STAMP 1 protocol). All studies were completed between 1995 and 1999. For 22 patients, mobilized peripheral blood (MPB) was initially purified by CD34$^+$ enrichment on Baxter Isolex beads and then sorted by FACS with anti-CD34 and anti-CD90 antibodies. Although ~50% of the CD34$^+$-enriched cells were keratinocyte-positive, none were positive after FACS. Two groups of patients received sorted CD34$^+$90$^+$ HSCs: (1) a group of 7 patients at Barbara Ann Karmanos Cancer Institute (BAKCI HSC), 100% of whom had stable disease after chemotherapy; (2) a group of 15 patients at Stanford University (SU HSC), 73% of whom had a complete or partial response and 27% had a stable disease after chemotherapy. A third group (SU MPB) consisted of 74 patients at SU who received unmanipulated MPB and resembled the SU HSC group, that is, 87% had a partial or complete response, 9% had stable disease, and 4% had progressive disease after chemotherapy. The estrogen- and progesterone-receptor profiles of tumors did not differ significantly among the patients in the three groups. Of the 15 Stanford patients at the last time point, 10 had died with relapse, 4 were disease free, and 1 was alive with relapse. All of the 7 BAKCI HSC patients died with relapse. Of the 74 patients at Stanford receiving MPB, 7 were alive, 5 without disease. The p values above the Stanford HSC curve were determined by 2 × 2 chi-square analysis of alive versus not alive patients at each time point, comparing Stanford HSC and MPB. At the last time point, in addition to $p < 0.01$ for overall survival, the chi-square for progression-free survival was $p = 0.04$.

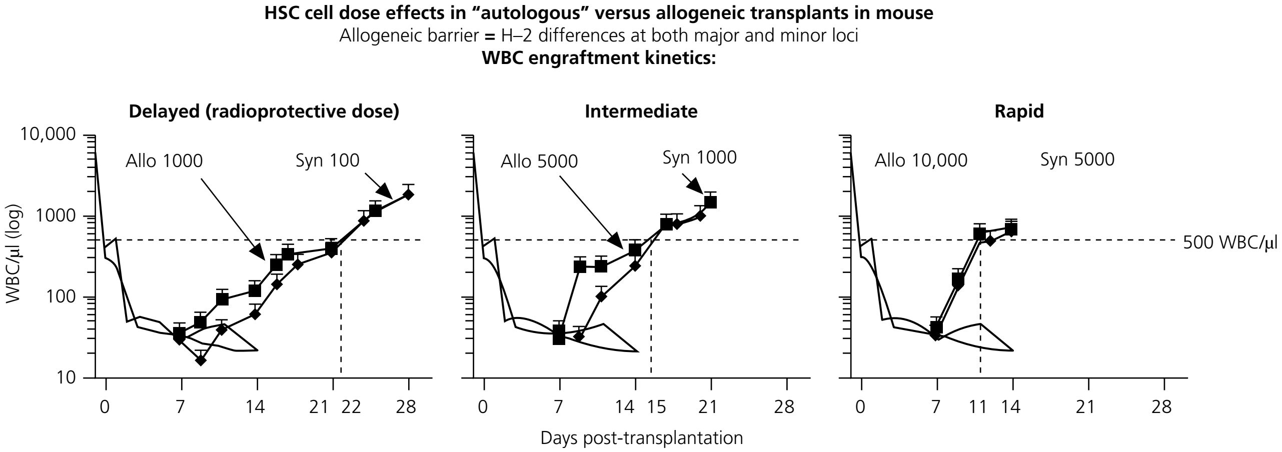

Figure 4.10 Engraftment kinetics of allogeneic versus congeneic purified hematopoietic stem cells (HSCs). Comparison of stem-cell dose required to achieve early hematopoietic recovery in syngeneic versus allogeneic irradiated mice. Syngeneic or allogeneic mice were transplanted with purified Thy-1^{lo}Sca-1$^+$Lin$^{-/lo}$c-kit$^+$ (KTLS) cells and bled on sequential days post-transplant. The kinetics of white blood cell (WBC) recovery were categorized into delayed, intermediate, and rapid recovery. Source: Adapted from Uchida et al. 1998 [394]. Reproduced with permission of John Wiley & Sons Ltd.

that have receptors which recognize them. Thus, a cell that facilitates engraftment of allogeneic HSCs might be a cell that presents MHC/peptide antigens to reactive T and NK cells without delivering a co-stimulatory signal, or induces the cells to undergo activation-induced cell death; and these same cells may be responsible for the veto of active CD4 and CD8 T cells that recognize and respond to them.

The immunosuppression of allogeneic HCT is largely due to the donor T-cell-mediated GVHD, which is by itself immunosuppressive. As discussed in Chapter 20, decreasing the number of T cells added to pure HSC allotransplants in a matched, unrelated donor (MUD) setting reveals no positive gain from added T cells either in antibody formation to new antigens, or cell-mediated immunity to a lethal viral infection in mice, that is, mouse cytomegalovirus (mCMV) [411–413]. At doses of T cells that give systemic GVHD, the host has little responsiveness, and less if the GVHD is ameliorated with immunosuppressive drugs. If the T-cell dose is under the level that gives systemic GVHD, T cells still home to lymph nodes via CD62L [414], and Peyer's patches and mucosal lymphoid tissue via integrin $\alpha_4\beta_7$ [415], where they are activated and carry out immune reactions that destroy these peripheral lymphoid organs as sites of immune responsiveness [412,413]. Activated T cells then home to the thymus, destroying the site of T-cell generation. It was not surprising, therefore, that the best antibody and T-cell responses occurred in recipients of pure HSC transplants; even better were responses when pure HSCs plus CMV-reactive T cells were co-transplanted [411].

The bane of clinical HCT in terms of infectious disease is the often lethal infections with *Aspergillus fumigatus*, CMV, and *Pseudomonas* [416]. Small numbers of each of these infectious organisms given to mice that have received HSC transplants can result in the morbidity and mortality that occurs in patients [416]. With the isolation of clonal CLPs, CMPs, and GMPs, cellular therapies for each of these disorders has been investigated. Co-transplantation of HSCs and CLPs can render mCMV infection non-lethal in both syngeneic and allogeneic protocols [279]. Co-transplantation of HSCs and CMPs and GMPs can prevent the lethal consequences of *Aspergillus* infections if the *Aspergillus* is given on day 9, 11, or 14 after HSC transplantation, and addition of G-CSF to these HSC/CMP/GMP transplant protocols prevents *Aspergillus* infections given just 3 days after transplantation [416]. Similar CMP *plus* GMP protocols are sufficient to eliminate *Pseudomonas* infections, and in both cases these treatments work in both the syngeneic and allogeneic settings.

Immunologic tolerance and HSC transplantation

It has been known since the pioneering work of Main and Prehn that bone marrow chimeras are usually transplantation tolerant to cells, tissues, or organs from the hematopoietic cell donor [372]. This method of induction of transplantation tolerance has been substantiated with pure HSC transplants [404,407], either in the high-dose or reduced-intensity setting, and whether the transplant is concurrent with the HSC transplantation or occurs months later [404,407]. Hematopoietic chimeras in humans are also usually specifically transplant tolerant of donor tissues, and trials for inducing tolerance with bone marrow cells in a reduced intensity but lymphoablative setting along with organ allografts from the bone marrow donor [417] should be followed with purified HSCs that are incapable of GVHD induction.

Reversing autoimmune diseases with disease-resistant HSCs

Partial or complete replacement of an autoimmune diabetes-prone hematopoietic system in mice with purified HSCs from diabetes-resistant strains of mice in the prediabetic period completely precludes progression to diabetes (see Chapter 18), whereas the same treatment of already diabetic hosts along with donor strain islet cell transplants cures the small numbers of mice undergoing this protocol [418]. These cures have also been accomplished in both the high-dose and reduced-intensity settings. Additionally, in a mouse model of systemic lupus erythematosis, Smith-Berdan et al. were able to achieve greatly increased overall survival by treating mice with established disease with reduced-intensity conditioning and transplants of MHC haplomismatched allogeneic HSCs [393]. Compared to control mice, those that received transplants exhibited stabilization or reversal of their lupus, including proteinuria and elevated circulating immune complexes or autoantibodies. These results indicate that induction of durable mixed chimerism by transplantation of purified allogeneic HSCs after reduced-intensity conditioning has the potential to reverse symptoms of established autoimmune disease.

The future of HSC transplantation: replacing myeloablative conditioning with selective depletion of endogenous HSCs and living donors with cell lines as donors

We have found that we can deplete not only T cells and NK cells with monoclonal antibodies, but also HSCs and some progenitors. Mouse HSCs require constant in vivo signaling of their c-kit receptors with endogenous, likely membrane-bound, kit ligand (KitL, SLF, or SCF) [70]. Treatment of immune-deficient mice with a blocking anti-c-kit antibody, called ACK2, leads to loss of HSCs, MPPs, CMPs, and so on, as well as precursors of melanocytes [101]. Following HSC depletion, transplantation of nearly syngeneic mice (i.e., of the same strain but with a green fluorescent protein (GFP) insert or strains congenic for CD45 alleles) resulted in ~15% chimerism, rather than the ~0.5% seen in untreated hosts. Repeating the antibody and HSC injections three times results in ~85% lifelong chimerism with donor cells [101]. Therefore, lymphoablative and HSC/MPP antibody depletions could replace chemoradiotherapy to create chimeras where the donor cells are healthy HSCs but not the host's HSCs.

Eventually, if we can generate transplantable HSCs from pluripotent stem cell lines, and other tissue stem cells from the same line, the HSCs could induce tolerance of the tissue that the other tissue stem cell produces. We are within years, rather than decades, of achieving these goals, at which time we will be in the era of regenerative medicine from stem cell lines.

Stem cell competition and natural chimeras

In some species, individuals can be linked together physically and exist as natural chimeras. Sponges are an example, but colonial tunicates are the best-studied example. These organisms are protochordates in the phylum urochordata, the most advanced of the invertebrates. When the individual is generated by sexual reproduction, the oozoid (egg-derived) embryo goes through the classical chordate intermediates of blastula, gastrula, and neurula, and is released from the mother colony as a tadpole with head, eyes, notochord, neural tube, and segmented musculature making up the tail. The tadpole swims to a nearby subtidal surface and metamorphoses to an invertebrate body plan, losing notochord, neural tube, and segmented musculature by apoptosis. The dying tissues are cleared by blood and tissue macrophages [419]. The oozoid, with a heart, gill arches, oral and anal siphons connected to a gastrointestinal organ, and a number of distinct blood cell types, is covered with a gelatinous tunic, and immediately begins to bud from its body wall a collection of cells, now known to be mainly somatic stem cells [420]. This group of stem cells organize without reproducing the blastula, gastrula, or neurula stages, into a blastozoid individual with an identical body plan to the mother from which it budded. The blastozoid undergoes vasculogenesis from the intracorporeal heart and blood vessels to form an extracorporeal blood system that connects, in the tunic, with the blood vessels from all other blastozoids in the common tunic. When two or more oozoids or blastozooid colonies on the same subtidal surface contact tunics, the ends of the extracorporeal blood vessels, called ampullae, extend and contact the blood vessels and ampullae of the other colony. Within a day of this contact, either the vessels anastomose to form a common circulation between colonies or an immune-based rejection between the vessels occurs, resulting in scar formation [421]. The fusion or rejection is mediated by a single highly polymorphic gene locus with hundreds of alleles [421]. Sharing one or both alleles leads to chimera formation, sharing none leads to scars between the colonies. These living natural parabionts undergo the budding cycle approximately every week, and the full life span of an individual from bud to senescence and death is about 3 weeks.

These colonies exchange somatic stem cells for each of the budding cycles, so that the individuals are themselves chimeras, but when the colonies begin the process of preparing for sexual reproduction by forming an ovary and a testis in each individual of a single individual derived or fused chimeric colony, the germline that develops from germline stem cells is usually dominated by one genotype rather than both genotypes in a megacolony between genetically distinct individuals [422]. Because of the high polymorphism of the histocompatibility locus, only kin – and usually siblings – share alleles and fuse vessels. The competition between somatic and between germline stem cells is therefore within a kindred. The full genome sequencing of the *Botryllus schlosseri* colonial protochordates has been completed, and the genomic sequence relationship of the blood system and other tissues is most like the vertebrate branches of the phylogenetic trees [423]. Therefore, in perhaps the best invertebrate to vertebrate link known, stem cells for soma and for germline exist and compete. Can this happen in the vertebrates?

In 1945 Ray Owen published that in freemartin cattle, wherein male and female twins can share a placenta, the offspring for life have blood systems from each other [424]. This finding underpins much of the research concerning both blood-forming stem cells and the development of self-non-self immune recognition that allowed the twins to “tolerate” each other’s blood cells (and as Medawar later showed, skin grafts) [425]. These findings led Burnet to propose the clonal selection theory of immunity, where each immunocompetent lymphocyte would be restricted to produce only a single type (but thousands of) immune receptors, so that anti-self clones could be eliminated during fetal development, and anti-non-self clones could be amplified by immunization to become “memory” cells [426].

The fact of tunicate stem cell competitions led us to search for HSC competitions, and the emergence of some clones that are selected for or against in aging [192]. We also tested and showed germline stem cell competitions in the developing mouse testis [427]. How, then, could competing stem cell clones play a role in the development of leukemias and other cancers?

Myelogenous leukemias are driven by leukemia stem cells (LSCs), which are at the oligolineage progenitor stages

Poorly regulated or unregulated self-renewal is a property that all cancers have, and we call those cells within a cancer that have self-renewal capacity cancer stem cells [112]. Therefore, the major distinguishing property of normal and neoplastic stem cells is their capability of self-renewal, so it becomes important to understand whether the pathways that lead to self-renewal are novel in normal HSCs or might be shared among different classes of tissue-specific multipotent stem cells, and might be acquired by cancer cell progenitors as they emerge as cancer stem cells [112].

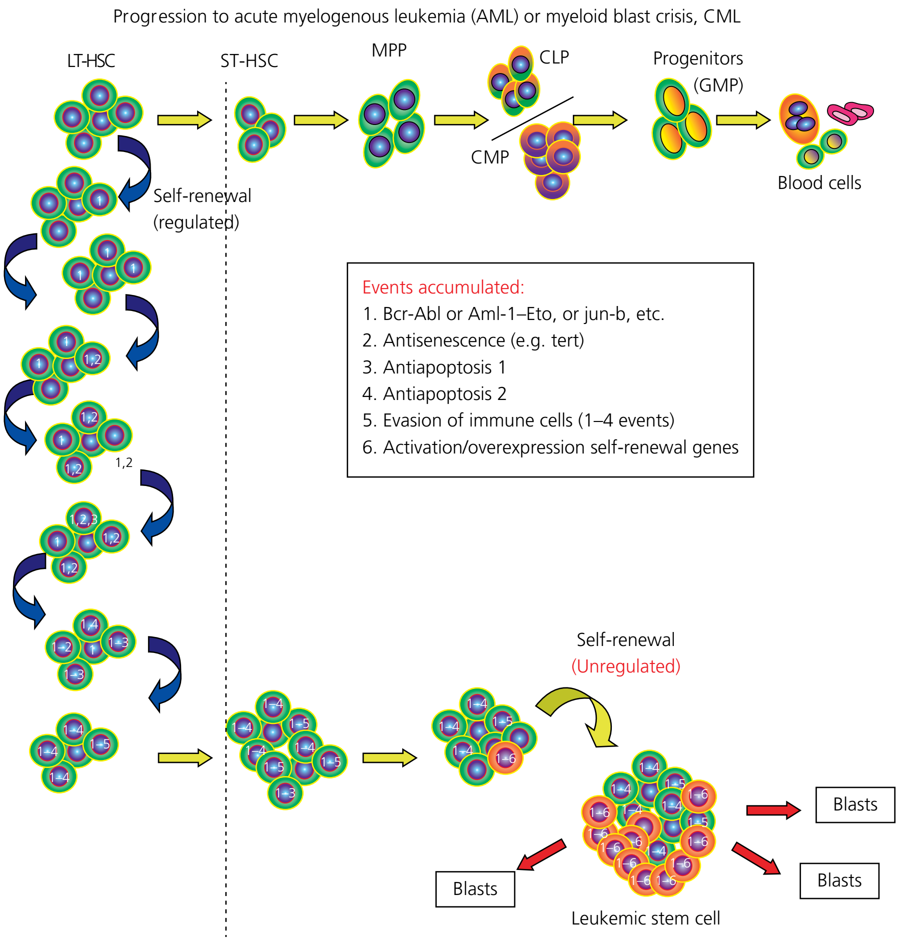
To understand the mechanisms of leukemic transformation, it is important to understand the life history of leukemic progression (Figure 4.11). If one views leukemia development as a series of steps in malignant progression, malignant self-renewal may be obtained through several transformation steps that include a block in differentiation, the retention or acquisition of self-renewal, and/or avoidance of programmed cell death by several independent cell-intrinsic pathways and by immunosurveillance of the intrinsic and adaptive immune systems.

A set of early stem/progenitor cells with extensive proliferation, or with reduced programmed cell death that are not yet malignant, may form “preleukemic” clones, and these clones may undergo additional oncogenic events that induce differentiation blocks at a progenitor stage to become leukemia. Many of the genes overexpressed in leukemias or cancers are driver genes for normal stem cell self-renewal without differentiation, such as *BMI1*, *PTEN*, *MLL*, *RUNX1* (for review see [428]).

Progression to myelogenous leukemias occurs in competitive HSC clones in a stepwise fashion involving both mutations and epigenetic events

Molecular markers for leukemia, including oncogenic fusion proteins resulting from leukemia-specific chromosomal translocations, have disclosed the multistep nature of acute leukemia development. A typical case is chronic myelogenous leukemia (CML). The CML-specific t(9;22) Philadelphia chromosome and its resultant *Bcr–Abl* fusion gene is present in all myeloid cells, erythroid progenitors, B cells, and rare T cells; thus it is a multipotent progenitor or HSC. We have shown that it is HSC clones which, during the myeloproliferative stage, outcompete normal HSC clones in the same patient. When the chronic phase of CML converts to myeloid blast crisis, the LSC is at the stage of the GMP in all cases studies [429]. These GMPs are driven by the β-catenin signaling pathway, and can be inhibited in their proliferation by transfection of axin, the natural inhibitor of signaling in this pathway. In 4 of 7 patients, GSK3β – the enzyme that normally phosphorylates β-catenin (in a complex with the adenomatous polyposis coli gene product and axin) in the cytoplasm – is misspliced so that it lacks the kinase domain in all GMP LSCs (and some HSCs). Furthermore, only these GMP clones, and not the HSCs, spread the disease and, in experiments, transplant the disease to immunodeficient mice [430].

There are many other examples of human adult and childhood leukemias that support the early acquisition of predisposing mutations that occur in HSCs which require additional events to result in leukemic transformation. The AML1-ETO chimeric protein that is the product of the t(8;21) translocate genomic region is continuously detectable in t(8;21) AML patients who maintain long-term remission for more than 10 years. Although these patients are clinically “cured,” AML1-ETO remains detectable in HSCs (Thy-1$^+$CD34$^+$Lin$^-$CD38), B cells, and erythroid and megakaryocyte colony-forming cells [400]. In all of these cells, only HSCs self-renew, setting up clones that can acquire additional proto-oncogenic events. In patients with childhood t(8;21) AML, AML1–ETO fusions are retrospectively detected in neonatal Guthrie spots [431], further suggesting that AML1–ETO fusion is at the level of HSCs (in some cases in utero). Acquisition of chromosomal translocations in utero is also demonstrated in infant t(4;11) and childhood t(12;21) acute leukemias. Clonotypic MLL–AF4 and TEL–AML1 genomic fusion sequences were demonstrated in neonatal blood spots from patients diagnosed with ALL [431–433]



Events accumulated:
1. Bcr-Abl or Aml-1–Eto, or jun-b, etc.
2. Antisenescence (e.g. tert)
3. Antiapoptosis 1
4. Antiapoptosis 2
5. Evasion of immune cells (1–4 events)
6. Activation/overexpression self-renewal genes

Figure 4.11 Comparison of stem cell self-renewal during normal hematopoiesis and leukemic transformation. During normal hematopoiesis, the signaling pathways that regulate self-renewal are tightly controlled, allowing proper differentiation to each of the mature blood cell lineages (top). Accumulation of mutations in the self-renewing hematopoietic stem cells (HSCs) over time until dysregulated self-renewal ability is attained and leukemia propagation is initiated. Dysregulation of self-renewal mechanisms in transformed cancer stem cells leads to uncontrolled self-renewal and the production of leukemic blast cells. The leukemic population capable of sustaining disease is often distinct from the blast population, and may reside in the stem cell or progenitor cell compartment. Importantly, if the transformation event occurs in a progenitor cell, it must endow the progenitor cell with the self-renewal, because the progenitors would otherwise differentiate. (For a color version of this figure, please see the color plate section.)

and in identical twins whose genomic fusion sequence was identical [382]. In these cases, t(12;21) ALL developed at ~10 years of age, indicating that cells with TEL-AML1 were present for more than 10 years before leukemic transformation. Further, TEL-AML1$^+$ ALL cells in twins sometimes possess identical IgH rearrangement, implicating in utero transfer of preleukemic cells. In childhood ALL, preleukemic B- or T-cell progenitors appear to persist over the long term: “leukemic clones” possessing clonal T-cell receptor or IgH rearrangements are reported to persist more than 3 years after onset of complete remission [434]; these might involve the only other blood cells that self-renew – memory T and B cells. These data strongly suggest that leukemic transformation commonly occurs by a multistep process. In mice and humans, the only cell in the myeloid lineage that self-renews over long periods of time is the LT-HSC [1]. The preleukemic clone should exist in the LT-HSC to sustain multiple mutational events over time. Therefore, it appears that the accumulation of mutations occurs as a precondition for leukemia, at the level of HSCs or progenitors that have gained the capacity of self-renewal.

We have shown that in 5 patients with AML and an internal tandem repeat mutation of the *FLT3* gene, individual HSCs can be found with 1, or 1 + 2, or 1 + 2 + 3, and so on genomic mutations (Figure 4.12) [84]. In all five cases the *FLT3* internal tandem repeat mutation is the penultimate event in the preleukemic HSC clone, with the leukemias emerging with LSCs at the MPP or LGMP stages [84] (see below). It is very interesting that in at least 2 of the 5 patients the first mutation was in one allele of *TET2*, and in both patients the second mutation to appear was in the other allele of *TET2* [84]. These mutations are in genes whose primary known functions are the oxidative hydroxymethylation of 5-methyl cytosine in DNA, an epigenetic mark, in the immediate vicinity of a gene, which usually prevents its transcription. Thus the ability of opening DNA sites that had been silenced is likely lost in these cells. Full analysis of the epigenome in these cells is currently not possible, as these early clones in preleukemic progression are too rare to elucidate with current biochemical techniques. Nevertheless, if the silenced loci are part of the differentiation program that operates in stem and progenitor cell undergoing continued proliferation, their silencing is likely to cause HSCs to expand.

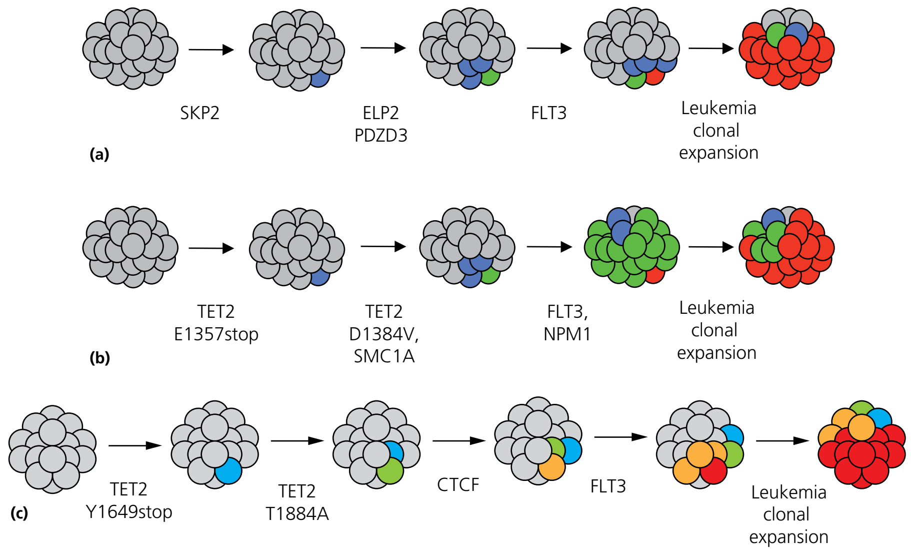


Figure 4.12 Clonal progression of preleukemic mutations in hematopoietic stem cell (HSC) clones, followed by emergence of the leukemia stem cell (LSC) in the multipotent progenitor (MPP) stage in three cases of FLT3td acute myeloid leukemia (AML) [84]. Exomic sequencing of the AML cells and T cells from the same patients allow listing of the mutations specific to the AML. Individual HSCs were isolated from the 3 patients and grown to colonies with hematopoietic growth factors, and the colonies analyzed with DNA primers specific for each of the mutations in the LSCs. Shown are the normal HSC clones (grey) and mutant HSC clones (with each successive color – blue, green, yellow – indicating the addition of a new mutation). Leukemic HSC clones (red) finally have all mutations. A TET2 loss of function mutation via a stop codon was the earliest preleukemic HSC event in 2 of the 3 patients (b) and (c). In the same individuals, the next event is the loss of TET2 by another stop codon in the other TET2 allele. Following that are clones with 3, or 4 or *n* mutations in the 3 patients. In all 3 the FLT3 internal tandem repeat occurred as the final mutation before the LSCs emerge. It is interesting that in 2 patients the loss of all TET2 function, which regulates CMEpG to hydroxymethyl cytosine, an epigenetic modifier of the CpG methylome, occurs before any of the other mutations. Final leukemic transformation can occur at the level of myeloid progenitors

Several lines of evidence show that final myeloid leukemic transformation can only occur at the level of progenitors that have acquired the property of self-renewal. In contrast, lymphoid cells include neoplastic cells with clonally rearranged T-cell receptor or immunoglobulin genes. Whereas myeloid progenitors and myelomonocytic cells are not self-renewing, lymphocytes that contribute to the memory pool are self-renewing. Thus, the final transformation to lymphatic neoplasms can occur in cells that already have regulated self-renewal capacity.

The search for LSCs involves the one property shared by all malignancies, the ability to initiate and spread the disease. Transfer of human AML to immunodeficient mice was first demonstrated to be limited to CD34$^+$CD38$^-$ or CD34$^+$CD71$^-$HLA$^-$DR$^-$ cells, and attributed to early progenitors such as HSCs [435]. We [400] and others have shown that in at least some AMLs, the LSCs lack CD90 expression. In our study of AML1/ETO AML, LSCs were in the MPP phenotype (CD34$^+$38^{lo}90$^-$Lin$^-$) [400]. Surprisingly, in the same patients, 1–40% of HSCs were t8;21$^+$, but these HSCs gave rise in vitro to normal myeloerythroid colonies, not leukemic blasts. As shown in Figure 4.11, these represent preleukemic clones; thus AML1/ETO may be necessary but not sufficient for full leukemic transformation.

A mouse model that expresses AML1/ETO driven by the MRP8 (GMP-, granulocyte-, and monocyte-specific) promoter did not develop leukemia. After the injection of a DNA alkylating mutagen, *N*-ethyl-*N*-nitrosourea (ENU), however, almost 55% of mice develop AML-M2 [436]. Similarly, PML/RARα is a product of the t(15;17) translocation, and MRP8$^-$PML/RARα transgenic mice develop acute promyelocytic leukemia (APL)-like disorders [437]. The frequency and rapidity of PML-RARα leukemias increases when they are crossed to MRP8–Bcl-2 mice [438]. In these mice the proto-oncogenes were present in all cells of the GMP lineage, allowing rare subsequent events to be fixed.

Inhibition of apoptotic pathways alone can allow leukemia development at progenitor stages. MRP8–Bcl-2 mice display increased numbers of mature monocytes, resembling CMML, but do not develop acute leukemia. However, an additional introduction of Fas (*lpr/lpr*) mutations into these mice results in transformation into AML in about 15% of progeny, but only if leukemia emerges by age 8 weeks [439]. The transplantable GMP stage leukemias are TERT^{++}, and overexpress CD47, and have acquired the property of self-renewal, implicating a multistep process. Even MRP8–Bcr-Abl mice have increased frequencies of conversions to acute blastic leukemias if crossed to MRP8–Bcl-2 strains.

The general rules so far are that mouse AML LSCs induced as described are at the stage of the GMP, as is human CML myeloid blast crisis [429,440–442]. Most human AMLs are at the level of the MPP and/or LGMP. No HSC-stage LSC has been found.

The identification and characterization of LSCs is crucial to the development of more effective treatment strategies. Ideal therapies will be those that target the LSC while sparing normal HSC, so identifying LSC-specific markers is an important strategy. To date we have identified several candidate LSC-specific markers, including CD96 and CD47 [149,443]. FACS analysis indicates that in many cases CD96 is expressed on the majority of CD34$^+$CD38$^-$ AML cells but on few, if any, normal HSCs (Lin$^-$ CD34$^+$CD38$^-$ CD90$^+$) [443]. Further, in four of five samples, only CD96$^+$ cells were able to propagate the leukemia in recipient immunocompromised mice, supporting CD96 expression on LSCs and its usefulness as a potential therapeutic target.

We identified CD47 in the mouse AML microarray screen, and have verified it as specifically upregulated in human AML. Subsequently, we found it to be expressed in all mouse models of myeloid leukemia we have examined. Most importantly, it is also expressed in LSCs and all leukemia daughter cells in human AML and blast crisis CML [41,149,444,447]. Oldenborg et al. have shown that CD47 is an age marker on mouse erythrocytes, acting as a "don't eat me" signal to macrophages [445]. The CD47 on cells signals macrophages via their SIRPα receptor, which upon ligation activates its ITIM motifs with tyrosine phosphorylation, triggering SH2-motif positive SHP1 and 2 tyrosine phosphatases. This activation results in the loss of cytoskeletal phosphotyrosines and their failure to enforce engulfment of particles or cells bound to the macrophage [446]. Transfected expression of CD47 is sufficient to allow a human myeloid leukemia cell line to evade phagocytosis by mouse macrophages in vitro, and to efficiently engraft immunodeficient mice in their hematopoietic tissues and develop into large tumors; control cells fail to engraft in immunocompromised $Rag2^{-/-}\gamma_c^{-/-}$[149]. Thus, CD47 does seem to play a role in the spread and/or life span of AML LSCs. These data also suggest that macrophage-mediated killing may be a significant player in leukemia surveillance. CD47, found to be overexpressed in mouse AML LSCs first, is now known to be overexpressed in all cancer stem cells and all human cancers tested [448–455].

There are increasing descriptions of mutations that occur at the post-translational and epigenetic levels and would not be detected by gene expression profiling. A study of 100 CML blood and marrow samples has demonstrated that, in comparison to normal GMPs, those from patients with CML blast crisis have higher levels of the active β-catenin in the nucleus and exhibit higher degrees of self-renewal in in vitro replating assays [429]. Dysregulation of microRNAs, small RNAs that bind to specific transcripts and either suppress their translation or target them for deletion, is another potential leukemogenic mechanism [457–460].

The important point here, as outlined in Figure 4.11, is that the elucidation of the phenotypes of normal HSCs and hematopoietic progenitors allows isolation of pure cell types, usually rare in the entire tissue, which can be assayed for their particular gene expression profiles, proteomes, histone changes, and DNA CpG methylation. These studies cannot be done with crude tissues such as whole leukemic bone marrow, $CD34^+$ leukemic, or MDS samples, etc. When done properly with highly purified subsets, the classification of the various types of LSCs, and the comparison of genes and gene transcripts between normal cells and their neoplastic counterparts have revealed a plethora of new and perhaps useful diagnostic and therapeutic targets undetected when whole blood or marrow populations are analyzed.

Programmed cell death and programmed cell removal are initiated by proto-oncogenic events, and all leukemias (and cancers) overcome both to become LSCs (CSCs)

Many terminally differentiated blood cells have a limited life span, for example, ~1–2 days for neutrophils. In mice with neutrophils that have extended life spans due to enforced expression of Bcl-2, surprisingly the homeostatic level of blood and tissue neutrophils does not rise with time, whereas $Bcl\text{-}2^+$ monocytes accumulate in the blood and spleen in a syndrome reminiscent of chronic myelomonocytic leukemia. If the neutrophils cannot die, how is their relative number maintained? It turns out that about 12–20 hours after migration of newborn bone-marrow neutrophils to an inflammatory site (e.g., the peritoneum after infusion of thioglycollate broth), wild-type neutrophils begin to undergo the intracellular events of apoptosis (e.g., DNA strand breaks). However, at this point, these cells have not yet "popped" open to release their cytoplasmic and nuclear contents (as is observed with isolated neutrophils in vitro) [51,461]. Nevertheless, Bcl-2 neutrophils not undergoing the early apoptotic events and wild-type neutrophils undergoing DNA strand breaks begin to be phagocytosed by macrophages 12 hours after migration. These cells are the population that follows neutrophils of acute inflammation [461]. We call this macrophage phagocytosis *programmed cell removal* (PCR), an event for preventing inflammation around dying cells, insofar as they pop inside macrophage phagolysosomes [52], not in tissue spaces. PCR is mediated by cell surface alterations on the target cell that express "eat me" signals such as phosphatidyl serine, calreticulin [462], and/or asialyglycoproteins for which macrophages have prophagocytic receptors. Adaptive immune responses can also bind tumors with antibodies or complement components that also serve as "eat me" signals. For example, human IgG1 and mouse IgG2 antibodies have Fc regions that are bound by the high affinity FcR found on macrophages (and NK cells). In summary, cells that are triggered to undergo programmed cell death are also triggered in a Bcl-2-independent process to undergo PCR [461]. Such triggers can be genotoxic stress, unbalanced protein synthesis, endoplasmic reticulum stress – events that can occur in the progression to cancer. We propose that cells involved in cancer progression (e.g., HSCs and myeloid progenitors in AML) sustain these lesions at a particular differentiation stage, and usually die from apoptosis. However, some HSC clones may have activated the antiapoptotic genes such as Bcl-2, and these clones would survive, except that they still could express eat me signals and undergo PCR. As stated earlier, all leukemias and cancers tested overexpress CD47, the "don't eat me" signal that overrides the "eat me" signals for PCR. At that point, the cells have not only escaped death, but also are free to migrate through tissue fields containing macrophages [452]. The upregulation of CD47 appears to be a late event in leukemogenesis.

Myelodysplastic syndrome is a stage of leukemic progression before programmed cell removal is overcome

Myelodysplastic syndromes (MDS) are a heterogeneous set of diseases wherein the patient, usually elderly, loses the ability to produce one or more terminal blood cell types but maintains highly proliferative bone marrow. MDS commonly progresses to AML. It has been associated with a variety of mutations such as $5q^-$, monosomy 7, mutations in ribosomal proteins, and so on (for review see [463]). It has been a mystery how such a diverse set of causes could lead to the same dysplasia with, for example, anemia or thrombocytopenia. We investigated a subset of MDS patients, mainly with monosomy 7, and discovered that MDS HSCs outcompete normal HSCs in patients and in NSG immune-deficient mice that receive transplants of MDS bone marrow or HSCs [464]. Thus, the MDS HSC clone is outcompeting the normal clone at the stem cell level. However, a hallmark of MDS is the depletion of progenitors such as the GMPs, erythroid progenitors, and megakaryocyte progenitors [464]. These $CD34^+38^+$ progenitors express high levels of calreticulin on their surfaces and are phagocytosed in vitro when co-incubated with macrophages. Phagocytosis could be inhibited completely with calreticulin peptides that block LRP1-mediated macrophage phagocytosis. These progenitors do not express CD47, but blasts in both refractory anemia with excess blasts and AML secondary to MDS express CD47 at high levels, allowing these cells to evade phagocytosis [464].

CD47, the "don't eat me" signal that overcomes programmed cell removal, is a target for antileukemia and anticancer therapies

As described earlier, CD47 provides a "don't eat me" signal to macrophages by acting as a ligand for the SIRPα receptor on macrophages [84,444,447–452,456,465–469]. We have obtained, made, and humanized blocking anti-CD47 antibodies that prevent CD47 ligation of macrophages. If the blocked CD47 is on a tumor cell adherent to a macrophage, the result is tumor cell phagocytosis and death in the phagolysosome [447]. This occurs both in vitro and, apparently, in vivo, as we have observed, in immune-deficient mice, the reduction in size or growth rate of primary human leukemia or cancer xenografts, ranging from breast cancer to glioblastomas [84,444,447–452,456,465–469]. CD47 was first discovered by comparing gene expression patterns between highly purified HSCs, MPPs, and LSCs at the MPP stage. Indeed, anti-CD47 is one of the earliest therapies coming from the identification, purification, and isolation of cell surface proteins selectively expressed on LSCs, and also CSCs [84,444,447–452,456,465–469]. At time of writing, various forms of CD47 blocking antibodies and proteins are being readied for early phase clinical trials. In addition, in a single experimental system, anti-CD47-enabled phagocytosis of a colorectal cancer cell line (DLD1, transfected with the chicken ovalbumin gene to be expressed in the cytoplasm) allows the macrophages to digest and cross-present the SIINFEKL peptide on mouse H2Kb macrophage cell surfaces in a way that cross-presents it to OT1 CD8 killer T cells in vitro and in vivo, but not to OT2 CD4 T cells [466]. This implies that CD47 allows cells to evade both macrophages of the innate immune system and T cells of the adaptive immune system. Whether monotherapy with anti-CD47 antibody will enable both arms of the immune system to target malignant cells will be examined in a subset of patients in phase I trials.

Conclusions

The development of a general method to prospectively isolate hematopoietic stem and progenitor cells [1,5,30] has made it possible to construct increasingly detailed lineage pathways from LT-HSC to mature blood cells. With the exception of memory T and B lymphocytes in the entire hematopoietic lineage, only LT-HSC self-renew, and this self-renewal capacity is tightly regulated [1]. The genetic regulation of HSC self-renewal includes regulation of programmed cell death, regulation of cell-division frequency, and regulation of transition to multipotent and to oligopotent progenitors. Gene expression analyses of prospectively isolated HSCs and progenitors provide insights into the mechanisms of self-renewal and lineage commitment. These same isolated HSCs and progenitors are increasingly useful in clinical HCT, whether to regenerate the myeloablated hematopoietic system in cancer patients, to condition allogeneic hosts for donor tissue or organ grafts, or even to replace an autoimmune-prone hematolymphoid system with a non-autoreactive donor population. Finally, the concept of self-renewal as the critical regulated event limited to HSCs in normal hematopoiesis has now been extended to the hypothesis that within leukemias and cancers are relatively infrequent populations of LSCs and CSCs that undergo poorly regulated self-renewal. Prospective isolation of LSCs should allow more direct approaches whereby immune and drug therapies target molecules restricted to these malignant stem cells. Both the preleukemic phase and the leukemic phase of the myeloid leukemias are shown to involve stem cell competitions, the early phase HSCs almost certainly for niche occupancy, and the later phase frank AML LSCs for ever more successful and drug-resistant clones. Thus, in the field of stem cells, the principal properties are self-renewal, regulated differentiation, migration, longevity even after many doublings, and competition for niches. This is true for normal HSC, abnormal HSC, and frank LSC clones.

CHAPTER 5

Marrow Microenvironment and Biology of Mobilization of Stem Cells

Michael P. Rettig, Mark A. Schroeder and John F. DiPersio
Washington University School of Medicine, St. Louis, and Washington University Medical School, St. Louis, MO, USA

Introduction

The habitat for hematopoietic cells within the bone marrow has now been dissected to the single cell level [1–4]. We are just beginning to understand the intricate interactions of cellular and non-cellular components of the microenvironment and hematopoietic stem and progenitor cells (HSPCs), which when normal are critical for health and when dysfunctional lead to disease. An understanding of the networks of interactions within this bone marrow microenvironment has provided important mechanistic information on normal hematopoietic and stem cell trafficking to, and egress from this environment. This understanding has led to improvements in approaches to hematopoietic stem cell mobilization and a better understanding of the pathogenesis of diseases such as acute myeloid leukemia and myelodysplastic syndrome.

Adult hematopoietic stem cells (HSCs) predominately reside in the bone marrow within a niche that is critical for hematopoiesis. Chemokines and cell surface molecules are critical intermediaries for the normal physiologic process of homing and egress of HSCs to and from the bone marrow. Altering this normal process through administration of supraphysiologic doses of cytokines or small molecule antagonists of key pathways has been the recent goal of hematopoietic cell transplantation (HCT) by using mobilized peripheral blood stem cells to engraft recipients. Currently, granulocyte colony-stimulating factor (G-CSF), granulocyte–macrophage colony-stimulating factor (GM-CSF), and the small molecule antagonist of the chemokine receptor CXCR4, plerixafor (AMD3100/Mozobil), are being used clinically to increase circulating peripheral blood stem cells with varying kinetics.

Under steady-state conditions, BM-derived HSPCs periodically leave the bone marrow niche and travel from the blood into multiple peripheral tissues, from the tissues into the lymphatic system, and from the lymph back into the blood, where they can either re-enter the BM or repeat the peripheral migration cycle [5,6]. The presence of small numbers of circulating HSPCs was first reported in the early 1960s [7,8] and the number of circulating HSPCs has been found to increase significantly in response to different stressful situations such as inflammation [9], organ/tissue damage [10–12], or strenuous exercise [13]. Pharmacologically mediated enforced egress of HSPCs from the BM microenvironment into the peripheral blood is called "mobilization," and this phenomenon has been exploited in HCT as a means to obtain HSPCs for hematopoietic reconstitution.

The term "mobilization" was first used in 1977 to describe a fourfold increase of peripheral blood granulocyte–macrophage colony-forming units (CFU-GM) after the administration of endotoxin to healthy volunteers [14]. One year earlier, high levels of circulating CFU-GM were observed in patients recovering from myelosuppressive chemotherapy [15]. Subsequent studies during the 1980s led to the development of a single high dose of cyclophosphamide as a generic mobilizing agent and the use of chemotherapy-mobilized HSPCs for transplantation [16–19]. During this same time period, while treating patients with recombinant human G-CSF to accelerate recovery from neutropenia after myelosuppressive chemotherapy, investigators observed that G-CSF, in addition to increasing circulating granulocytes, also mobilized HSPCs into the peripheral blood that were capable of providing long-term multilineage reconstitution capacity following transplantation [20–22]. The labeled indications for G-CSF were subsequently expanded to include the mobilization of HSPCs into the peripheral blood for collection and HCT.

In order to understand the biology of mobilization an understanding of HSPC homing and the environment that nurtures HSPCs is required. Using an anatomical approach, location near endosteum or endothelium has come to define two niches. This simplified approach likely underestimates the plastic and overlapping nature of the environment. Some of the critical components involved in trafficking and homing of HSPCs to these niches are chemokines, integrins, and selectins. This chapter will review the critical components of the stem cell niche and how stem cells home to, interact with, and are released from the marrow microenvironment during mobilization. The mechanism of mobilization and critical axes such as CXCR4/CXCL12, VLA-4/VCAM-1, stem cell factor, proteases, complement, and bioactive sphingolipids will be discussed.

Stem cell homeostasis and the components of the bone marrow niche

Niche is used to refer to the in vivo microenvironment that harbors adult hematopoietic stem cells, and regulates their renewal, differentiation, and survival [23]. The concept of a niche was initially proposed in 1978 by Schofield [24]. The idea that the environment could govern the fate of hematopoietic stem cells was controversial at the time and was counter to the argument that stem cell behavior was cell autonomous [25]. Numerous groups have confirmed the importance of a heterogeneous group

of cells, generically referred to as stroma, and extracellular matrix (ECM), which specializes in governing stem cell behavior. Just as the heart or lungs have a scaffolding of stroma and ECM to allow the normal development of the mature functional organ, the bone marrow contains a scaffold of stromal cells and ECM that are critical for the development of normal blood and maintenance and regeneration of hematopoietic stem cells. Modification of certain molecules or cells within the microenvironment can lead to alterations in proliferation, differentiation, and egress of hematopoietic stem and progenitor cells [26–28].

Regional differences within the bone marrow

The components of a niche

The specialized microenvironment of the bone marrow contains a number of cellular and non-cellular components that make it hospitable for HSPCs. Bone marrow stroma is made up of adipocytes, macrophages, vascular endothelial cells, mesenchymal stem cells, smooth muscle cells, and CXCL12-abundant reticular cells. These stromal cells produce components of the ECM such as fibronectin, hyaluronan, collagen, laminin, chondroitin sulfate, heparin sulfate, and glycosaminoglycans. The stroma and ECM interact with HSPCs through direct contact with cell surface receptors, secreted factors such as cytokines, and adhesive ligands such as hyaluronan. The major known components of the niche and their role in HSPC homeostasis and mobilization are outlined in Table 5.1. Interactions of HSPCs with niche components can be physical, structural, humoral, paracrine, metabolic, and neural.

Classically the marrow environment has been separated anatomically into two niches: perivascular [29,30] and endosteal [31–33] (reviewed in [30,34–37]). Location alone is not sufficient to be considered a niche, but functional properties to enable stem cells to survive, proliferate, and renew are essential to defining the niche. There is a symbiotic relationship that exists between stem cell and niche components. The dynamics between HSC and niche have been recently demonstrated using real-time imaging [2,3,38,39]. Location of HSPCs seems to depend on the degree of maturation with more immature cells and those that respond to damage signals located near the endosteum [2,3]. Within the unprovoked niche, most HSCs are quiescent (some estimates indicated up to one quarter of long-term HSCs can be cycling at any given time [40]), but after irradiation and transplantation HSPC cycling increases to as much as 50% [41]. Entry into the cell cycle is regulated by a number of mechanisms. Regulation of HSC differentiation is critical to prevent stem cell pool exhaustion [42]. Contact with osteoblasts and extracellular matrix glycoprotein, such as osteopontin, prevents exhaustion by inducing quiescence [33,43,44]. When HSPCs leave the bone marrow as occurs with peripheral blood stem cell mobilization, circulating HSPCs may be induced to cycle and lose their long-term repopulating capacity; however, the majority remain quiescent and retain the ability to engraft NOD/SCID mice [40,45,46]. On average, 1–5% of the stem cell pool enters the circulation daily [47]. Intriguing data suggests that there may be competition for a limited number of available niches [47]. The availability of these niches can be affected by mobilization using plerixafor alone or G-CSF + stem cell factor (SCF) [48]. Normal HSCs may also have to compete for the niche with malignant cells and this could affect mobilization and stem cell reserve [38,39]. The exact series of events that occur to result in HSPC mobilization under resting and provoked conditions, such as inflammation and peripheral blood stem cell mobilization, are just beginning to be understood and exploited for clinical use.

Perivascular niche

The bone marrow is a rich network of sinusoids. The vascular niche is in proximity to vascular endothelium. Cellular components of this niche in addition to endothelial cells include nestin$^+$ MSCs, *Lepr*-expressing perivascular stromal cells, sympathetic neurons, and CXCL12+ adventitial reticular cells (CARs) [29,49–53]. The concept of a vascular niche is supported by the observation that sites of extramedullary hematopoiesis such as the spleen and liver are devoid of bone yet can maintain HSCs. In addition, endothelial cells isolated from non-hematopoietic organs grown in culture can maintain stem cells [54]. In mobilized mice, HSCs, defined by CD150$^+$CD48$^-$, associate with sinusoidal endothelium in both bone marrow and spleens [29]. Finally, in non-irradiated mice, HSCs are in close proximity to vascular endothelium [2,3,39].

The divide between vascular and endosteal niche is arbitrary and the highly vascular endosteum supports HSCs that reside adjacent to endothelium which also associates with N-cadherin$^+$ pre-osteoblasts [2]. Alterations in this niche through damaging ionizing radiation result in leaky sinusoids and increased CXCL12 levels, and can significantly impact the engraftment of HSCs near bone or vasculature [2,3]. Non-irradiated recipients engraft HSPCs randomly between vascular and endosteal sites and irradiated recipients engraft preferentially near the endosteum. CXCL12, also known as stromal-derived factor-1 (SDF-1), is one of the best described chemokines that plays a central role in HSPC trafficking, homing, and retention in the bone marrow. A gradient of expression within the marrow between endosteum (high) and endothelium (low) can be altered for the purpose of mobilization through the administration of G-CSF [55] or manipulated through small molecule inhibitors of its receptor, CXCR4 (see mobilization section later).

Another component of the vascular niche are nestin$^+$ MSCs, which have been shown to associate with sinusoidal endothelium and are critical for HSC maintenance [50]. In close association with these cells are also CXCL12 adventitial reticular cells (CARs), which are perhaps the highest producers of CXCL12 and have been identified within the endovascular and endosteal niche [30]. CAR cells appear closely related to a CD146$^+$ adventitial reticular cell associated with sinusoidal endothelium [56]. Evidence suggests that perhaps these cells are coordinated through the sympathetic nervous system, which is closely associated with endosteal and perivascular niches [52]. Normal circadian oscillations in sympathetic tone and disease states such as diabetes may affect the sympathetic nervous system interaction with nestin$^+$ MSCs and alter mobilization through alterations in CXCL12 [52,57,58] (see mobilization section).

Although CXCL12 is a critical factor produced in the perivascular niche another component appears to be stem cell factor (SCF). Endothelial cells and newly described *Lepr*-expressing perivascular stromal cells are the primary producers of SCF, which is critical to the maintenance of stem cells [53]. Disruption of c-kit (receptor for SCF) is known to affect maintenance and engraftment of stem cells. Finally, other components important for normal leukocyte and HSPC migration, homing, and mobilization that are expressed on endothelium include selectins and integrins. The integrin VLA-4 has been perhaps one of the best studied. Both the α_4 and β_1 subunits of VLA-4 have been inactivated in mice. Lack of α_4 or β_1 integrin is embryonic lethal due to non-hematologic defects [59–61]. Conditional genetic ablation of α_4 integrin in both hematopoietic and non-hematopoietic compartments induced an eightfold increase in the number of circulating HSPCs (CFU-Cs) at 2 weeks

Table 5.1 Components of the niche and their role in mobilization

Cell / Factor / Receptor	Identity / Source	Role / Mechanism	Reference
Cells			
Osteoblast lineage	Endosteum lining cells N-cadherin+ CD45–	Decrease numbers results in decreased cellularity and extramedullary hematopoiesis. Alterations in CXCL12 expression leads to mobilization. Constitutive activation of PTH receptor increases HSC.	[31,33,55,68,69]
Osteocytes	Terminally differentiated osteoblasts	Knock out of G-protein receptor alpha from osteocytes leads to increased G-CSF-mediated myelopoiesis.	[67]
Osteoclasts	Endosteum lining cells resulting in bone resorption	Decrease results in increase trabecular bone formation, decreased # HSCs, decreased engraftment, and increased mobilization of HSC.	[70–72]
Macrophages	M-CSF receptor+, CD169+	Decrease leads to HSC mobilization.	[82,83,114]
CXCL12 adventitial reticular cell	Adipo-osteogenic bipotential progenitor CD45–, Ter119–, CXCL12++, CD44+, CD51+, VCAM-1+, PDGFRa and b+ ?CD146+	Apoptosis of CXCL12 expressing cells by diphtheria toxin treatment of transgenic mice leads to reduced HSC bone marrow numbers, increased HSC quiescence, and increased HSC in peripheral blood.	[49,56] [78]
Nestin+ MSC	Nestin+ peri-vascular cells CD45– CD31– CD34– VE-cadherin–	Regulated by SNS and parathyroid hormone. High expression of CXCL12. Decrease leads to decreased HSC number, decreased homing, increased EM hematopoiesis.	[50]
Lepr-expressing perivascular stromal cells	Nestin–, ***Lepr+***, peri-vascular cells		[53]
Sympathetic neuron		Beta adrenergic tone can regulate nestin+ MSCs. Inhibition increases mobilization.	[51,52,57,58]
Sinusoidal endothelial cell	CD45– CD31+ Sca-1+ Ter119–	Producer of SCF,	[29]
Adipocytes		Decrease increases trabecular bone, HSC numbers and engraftment.	[86]
Small molecules			
Oxygen	Oxygen tension near bone 10 mmHg	Hypoxia induces CXCL12 expression through HIF1α.	[89]
Calcium	Calcium ions concentrated near bone	Calcium ions are concentrated along bone and sensed through calcium receptors on HSCs.	[32]
Syphingosine-1-phosphate	Bioactive lipid, S1P levels highest in RBCs	S1P gradients may play a role in stem cell mobilization.	[272,278,280]
Cytokines / chemokines and other factors			
CXCL12 (SDF-1)	Osteoblasts, CAR cells, endothelial cells, nestin+ MSC	Gradient-induced chemotaxis and upregulation of integrins and CD44 on HSCs. Homing, retention and mobilization. HSC maintenance. Gradient affected by G-CSF.	[55,84,104,105]
IL-8 (CXCL2)/ (CXCR1 and 2)		Induces release of proteases.	[282,283]
Proteases (MMP-9, NE, Cathepsin K)		MMP-9: Cleaves mKitL and releases sKitL. NE: Cleaves CXCL12. Cathepsin K: Bone resorbing, cleaves CXCL12 and SCF.	[72,75,78,127,147,153]
Complement cascade	Classical (Ig-mediated) and non-classical pathways	C5 cleavage fragment and distal complement cascade is required for G-CSF and CXCR4 inhibitor mobilization.	[268–274,284]
Osteopontin		Produced by osteoblasts and binds CD44 on HSC to cause quiescence.	[43,44]
Stem cell factor (SCF) (soluble and membrane-bound c-kit)	Osteoblasts, endothelial cells, nestin+ MSC	HSC maintenance.	[53,285,286]
Thrombopoietin (TPO)	Osteoblasts	Stem cell quiescence and maintenance.	[287,288]
Angiopoietin-1	Osteoblasts and nestin+ MSC	Stem cell quiescence and maintenance.	[73]
Notch ligands	Endothelial cells, osteoblastic cells	Binds Notch on HSC to cause quiescence. Increased expression post-PTH causes increased HSC numbers. Not essential for HSC maintenance.	[33,289,290]
Prostaglandins	PGE2	HSC homing survival and proliferation. NSAIDs have been used to augment mobilization.	[291]
Cell surface receptors			
CD44		Binds hyaluronan and osteopontin.	[107–109]
CD62E and L (E- and L-selectin)		Expressed on endothelium (E) and leukocytes (L), essential for endothelial transmigration.	[101,292]
LFA-1 (CD18/CD11a)/ I-CAM		Integrin critical for IL-8-induced mobilization, mediates endothelial adhesion and transmigration.	[293]
VLA-4 (CD49d) / VCAM-1		Endothelial transmigration.	[101–103,110–112,166]
VLA-5 (CD49e) / VCAM-1			
CXCR4	Expressed on HSPCs, lymphocytes and megakaryocytes.	Binds the chemotactic factor CXCL12 (SDF1). Blocked by plerixafor.	

CAR, CXCL12 adventitial reticular cell; NE, neutrophil elastace; MMP-9, matrix metalloproteinase 9; NSAIDs, nonsteroidal anti-inflammatory drugs; Ig, immunoglobulin.

after deletion [62]. Similar HSPC mobilization was reported following conditional deletion of α_4 integrin in hematopoietic and endothelial cells [63]. In separate competitive transplant studies, $\alpha_4^{-/-}$ BM cells exhibited impaired homing to the BM, increased numbers of circulating CFU-Cs, and a competitive disadvantage in both short-term and long-term hematopoietic reconstitution compared to normal competitors [62–64]. Likewise, genetic ablation of β_1 in both the hematopoietic and non-hematopoietic systems of β_7-deficient mice resulted in an eightfold increase in the number of circulating HSPCs [65]. These data suggest that expression of α_4 integrin on HSPCs plays an important role in their retention within the BM microenvironment.

Endosteal niche

Osteoblasts support the growth of HSCs [66] and regulate their numbers [31,33]. The endosteal niche is defined by proximity to trabecular or cortical bone. One of the initial sites of HSC homing after transplant is near the endosteum [4], and this homing is influenced by radiation effects on the stroma [2,3]. The critical cellular components that create the endosteal niche include osteoblasts, osteocytes, osteoclasts, and nestin$^+$ MSCs [31,33,50,55,67–72]. HSCs interact with N-cadherin$^+$ osteoblasts [31] and these interactions are dependent on Angiopoietin-1/Tie2 tyrosine kinase receptor regulating stem cell quiescence [73] and Jagged 1/Notch signaling to increase HSC numbers [33]. Osteoblasts are critical for maintaining stem cell number and losses of osteoblasts result in decreased numbers of HSCs [31,33,74]. In addition, committed osteoblast cells known as osteocytes, which lie deep within the bone matrix, can affect hematopoiesis. Perturbations in osteocyte function can also alter the niche and affect HSC development through a G-CSF-mediated mechanism [67]. On the other hand, bone-resorbing osteoclasts, are important for stress-induced mobilization of HSCs through matrix metalloproteinase-9- (MMP-9) and CXCR4-dependent mechanisms [72]. Osteoclasts release the protease cathepsin K during inflammation resulting in cleavage and inactivation of SDF-1 and mobilization. Knockout of cathepsin K results in decreased bone marrow cellularity and extramedullary hematopoiesis [75]. Inhibition of osteoclast function through bisphosphonates decreases stem cell numbers and impairs engraftment [70]. Another critical role of osteoclasts is calcium production from bone, which maintains a gradient of high calcium near bone that is sensed by calcium receptors on HSCs [32]. Finally, nestin$^+$ MSCs have been found associated with endothelial sinusoids as mentioned earlier as well as lining bone consistent with their multilineage potential [50]. Mobilization with G-CSF directly alters osteoblast production of CXCL12 [55] and can affect nestin$^+$ MSCs as will be described later under mobilization.

The endosteal niche also includes non-cellular components including extracellular matrix and cytokines (Table 5.1). These extracellular components are important for regulating HSC numbers and proliferation. Osteopontin is a pleotropic glycoprotein produced by osteoblasts that negatively regulates HSC pool size [43,44]. It is through direct contact with receptors on the surface of HSCs such as CD44 and α_4 integrin that osteopontin mediates its effects. In addition, calcium ions that are concentrated near the bone surface can regulate HSC homing and engraftment through direct interaction with calcium receptors expressed on the surface of HSCs [32]. The loss of the calcium receptors on HSCs results in a decrease in bone marrow derived HSCs and affects homing to the endosteal niche. Other non-cellular factors regulating trafficking, proliferation, and survival include cytokines and proteases secreted by osteoblasts, endothelial cells, and stromal cells. A prototypical cytokine critical for stem cell maintenance and engraftment is stem cell factor (SCF) also known as Kit ligand or steel factor. Soluble SCF is secreted mostly by endothelial cells and specialized MSCs [53]. SCF exists as a soluble form (sKitL) and a membrane-bound form (mKitL). mKitL acts to bind HSCs and maintain quiescence and has antiapoptotic effects. SCF levels within the marrow microenvironment can be altered by a number of mechanisms. Cytokines such as G-CSF, IL-8, or vascular endothelial growth factor (VEGF), result in induction of matrix metalloproteinase-9 (MMP-9) which cleaves mKitL and leads to release of stem cells from the osteoblastic niche and increased proliferation [76–78]. Inhibition of SCF binding to HSCs allows engraftment of donor HSCs into previously occupied niches [79]. Other cytokines found in the microenvironment such as thrombopoietin [80], Flt3 ligand, IL-3, and the colony-stimulating factors G-CSF and GM-CSF, play critical roles in stem cell homeostasis, signaling differentiation and self-renewal and, as described later, can be involved in HSPC mobilization.

A unifying theory of niches

In reality the distance between vasculature and osteoblasts is in the order of 10–20 μm [3], this means as few as 1–2 cell diameters apart (recall a red blood cell is typically 6–8 μm). This proximity suggests the possibility for paracrine effects on HSPCs in either location. Coordinated, multidimensional interactions between vasculature, mesenchymal, and endosteal cells is likely to occur in the bone marrow, and future systems biology approaches may help to define the critical interactions between all components of the marrow microenvironment and HSCs. Critical interactions with the niche may allow for novel therapeutic interventions targeted to molecules and pathways.

Insight into the interdependency of the aforementioned niches comes from studies to find the common progenitor of the niche. In mice, the bone marrow niche does not develop without CD45$^-$ Tie2$^-$ CD105$^+$ Thy1.1$^-$ cells forming a cartilaginous matrix and undergoing ossification [81]. An ectopic niche can be generated by transplanting fetal bone isolated CD45$^-$ Tie2$^-$ CD105$^+$ Thy1.1$^-$ cells or via adult CD146$^+$ MSCs [56,81]. These ectopic niches require ossification and vascularization prior to engraftment of HSCs supporting the interdependency of niches.

One cell type common to both niches as mentioned earlier is the nestin$^+$ MSC. Nestin$^+$ MSCs have been reported to closely associate with sympathetic neurons and are located primarily perivascular and to a lesser extent near the endosteum. The sympathetic nervous system produces adrenergic signals that affect nestin$^+$ perivascular mesenchymal stem cells and regulates mobilization of HSCs [50–52]. The nestin$^+$ MSCs produce CXCL12 and their proliferation is inhibited by G-CSF administration. Expression of genes involved in HSC retention in the bone marrow such as CXCL12, SCF, and angiopoietin-1 are downregulated by G-CSF and adrenergic stimulation. Mobilization of HSPCs can occur through adrenergic signaling to nestin$^+$ MSCs that directly interact with HSCs. A further level of regulation bridging niches comes from CD169$^+$ bone marrow macrophages and monocytes which negatively regulate nestin$^+$ MSCs [82], express the G-CSF receptor and are important intermediates for G-CSF-induced mobilization [83]. One final cell type that deserves mention as an intermediary cell is the CXCL12-abundant reticular cell, which is the highest producer of CXCL12 and may be directly affected by stem cell mobilizing agents [84], and maintains early B-lymphoid progenitors [85].

As humans age the bone marrow is increasingly replaced by fat. The fat-producing adipocytes are not just fillers of space in the

Table 5.2 Mobilization agents and their mechanism

Agent	Mechanism	Kinetics	Reference
BIO5192	VLA-4 antagonist	<30 min	[264]
AMD3100/ Plerixafor	Bicyclam small molecule antagonist of CXCR4	Peak in 3–4 h	[207,221,294]
G-CSF	Downregulation of CXCL12 in BM osteoblasts, and minor release of proteases	Peak in 4–5 days	[68,153]
GM-CSF	Exact mechanism unknown but, alterations in adhesion molecules on HSCs may play a role	Peak in 5–7 days	[295–297]
Groβ/CXCL2	CXCR2 agonist and induces protease release, i.e., MMP-9	<15 min	[298,299]
IL-8/CXCL8	CXCR1 and CXCR2 agonist and results in release of proteases, i.e., MMP-9	<15 min	[282,283]
SCF	Binds and stimulates c-Kit	Mobilization in days to weeks, synergizes with G-CSF	[168–172]

marrow but have been shown to be another cellular mediator of HSPCs. As numbers of adipocytes increase in bone marrow the hematopoietic activity of the marrow decreases [86]. This effect may be partly related to adipocyte suppression of the endosteal niche by decreasing trabecular bone formation [86].

Non-cellular factors, acting in a humoral, paracrine or metabolic fashion, that play a role in retaining HSPCs in the bone marrow include oxygen, calcium ions, CXCL12, complement factors, and bioactive lipids: sphyngosine-1 phosphate and ceramide-1-phosphate. An oxygen gradient exists between the vasculature and the endosteum. Hypoxia is known to play an important role in HSC quiescence and long-term repopulating potential [87,88] and affects CXCL12 expression by stroma [89]. As oxygen tension increases HSCs are stimulated to cycle and expression of factors associated with quiescence decrease such as calcium receptor, N-cadherin and Notch-1. The key sensor of oxygen tension in the bone marrow is hypoxia-inducible factor-1 alpha (HIF1α). HIF1α directly regulates CXCL12 expression in endothelial cells [89]. Stabilization of HIF1α is a strategy that can improve stem cell mobilization [90]. The CXCL12/CXCR4 axis, complement, and S1P will be discussed extensively in more detail later and are summarized in Table 5.2.

In conclusion, a number of cellular and non-cellular factors acting through direct structural or physical ways or indirectly through humoral, paracrine, metabolic, or neurologic ways regulate the bone marrow environment and are targets for inducing HSPC mobilization, which will be discussed later.

HSC homing and engraftment

Homing to the bone marrow and mobilization can be thought of as interrelated processes sharing common pathways. The niche described earlier allows for entry and egress of HSPCs under homeostatic, supraphysiologic (such as mobilization), and pathologic (such as chronic inflammation) conditions. An understanding of what attracts HSPCs to the bone marrow has led to improvements in mobilizing HSPCs from the bone marrow.

The best-studied component of homing and mobilization is the CXCR4/CXCL12 axis. The chemokine CXCL12 (also known as stromal derived factor-1 (SDF-1)) is the ligand for the chemokine receptor CXCR4, which is expressed on stem cells, T cells, B cells, and megakaryocytes. A number of bone marrow stromal cells express CXCL12, which is essential for HSC homing to the bone marrow [85,91]. Alterations in the gradient of CXCL12 that exists in the marrow, or, direct pharmacologic blockade of its receptor, CXCR4, results in HSPC mobilization (see mobilization section).

Targeted disruption of either CXCL12 or CXCR4 is embryonically lethal in mice, resulting in very similar developmental defects, including the failure of HSPC migration from the fetal liver to the BM, defects in lymphoid and myeloid hematopoiesis, and cerebellar dysgenesis [92–95]. Mice transplanted with CXCR4-deficient progenitor cells exhibit increased numbers of circulating immature granulocytes, CFU-Cs (30-fold increase), and $\text{Lin}^{-}\text{Sca-1}^{+}\text{c-kit}^{+}$ (LSK) cells compared to animals injected with wild-type cells [55,91,96,97]. In separate competitive transplant studies, $\text{CXCR4}^{-/-}$ BM cells exhibited impaired engrafting capacity, with fivefold more $\text{CXCR4}^{-/-}$ BM cells being required to achieve engraftment levels similar to wild-type BM cells [98]. Consistent with the phenotype of mice reconstituted with $\text{CXCR4}^{-/-}$ cells, conditional ablation of CXCR4 in mice using the Cre-loxP recombination approach caused a severe defect in B-cell lymphopoiesis and a significant increase in the number of peripheral LSK stem cells [84,98]. In both of these conditional ablation studies, primitive hematopoietic stem cells (LSK cells) were retained in the bone marrow and became hyperproliferative following CXCR4 inactivation [84,98]. This observation demonstrates that HSPCs can be retained in the BM microenvironment through a CXCR4-independent mechanism. Furthermore, the hyperproliferative state of LSK cells following CXCR4 ablation indicates that CXCR4 acts intrinsically in primitive HSPCs to enforce quiescence [98].

The homing of stem cells to the bone marrow is a multistep process of rolling, adhesion, diapedesis, and transmigration [99–102]. Factors involved in the normal homing of HSCs after transplant include: selectins (E- and L-selectin) and integrins (VLA-4) for endothelial rolling and CXCL12 for transmigration [101–103]. These factors play dual roles in homing and mobilization. A gradient of CXCL12 causes chemotaxis of stem cells and homing and engraftment of HSCs in mice and is dependent on expression of the chemokine receptor CXCR4 [104,105]. Once in the bone marrow, exiting circulation (rolling and diapedesis) is mediated by CXCL12 signaling resulting in increased expression of VLA-4, VLA-5, and LFA-1 on stem cells [102,103,106]. Tropism of bone marrow sinusoidal endothelium specifically facilitating HSC diapedesis has been reported [106]. An additional mechanism facilitating HSC homing based on CXCL12 is a conformational change in the HSPC and enrichment of CD44 at the tip of cellular projections [107]. This selective expression of the glycoprotein receptor for hyaluronic acid (HA) can act as a ligand for E- and L-selectins [108,109]. HA is expressed on bone marrow endosteum and endothelium and may act as one of the initial tethers for HSCs expressing CD44 as they traffick to the bone marrow [107]. Finally, blockade of integrins (VLA-4 ($\alpha_4\beta_1$ integrin)), VCAM-1, or CD44 prevents homing of HSCs [110–112]. Studies using blocking antibodies have demonstrated that VLA-4 and VCAM-1 play an important role during the migration of HSPCs to, and retention in the bone marrow [110,111]. One final alteration that affects homing is damage to the microenvironment through irradiation, which results in increased CXCL12 mRNA levels within bone marrow-depleted trabecular bone areas. This results in preferential trafficking of HSCs to trabecular bone areas [2]. These areas are likely to be critical anatomic areas of HSC homing and expansion after transplant.

HSPC mobilization via ablation of niche cell subsets

Studies have shown that ablation of different niche components results in HSPC mobilization. Conditional ablation of endosteal osteoblasts in Col2.3Δ-TK transgenic mice by ganciclovir administration [69,113] or in osteocalcin-diphtheria toxin receptor (Oc-DTR) transgenic mice by diphtheria toxin treatment [57] resulted in mobilization of HSPCs and the depletion of a wide range of hematopoietic cells from the bone marrow, including HSPCs. Similarly, depletion of nestin$^+$ MSCs by inducible expression of diphtheria toxin receptor in nestin-expressing cells caused the mobilization of approximately 50% of HSPCs to the spleen [50]. Finally, two recent studies showed that ablation of bone marrow mononuclear phagocytes results in HSPC mobilization. First, Chow et al. [82] used four different models to deplete different types of monocyte/macrophage cell populations from mouse bone marrow. These models included clodronate-containing liposomes, an inducible c-fms promoter driven Fas-mediated cell depletion model (macrophage Fas-induced apoptosis (MAFIA)), and transgenic animals with DTR driven by CD11b or CD169. In each model, monocyte and/or macrophage ablation was associated with HSPC mobilization. Winkler et al. [114] observed similar HSPC mobilization following monocyte/macrophage depletion with the clodronate liposome or MAFIA mouse models. However, the mechanism(s) whereby monocyte/macrophage depletion induces HSPC mobilization is controversial. Chow et al. [82] observed decreased expression of CXCL12, SCF, Ang-1, and VCAM-1 mRNA in nestin$^+$ MSCs, but not osteoblasts, following phagocyte depletion. Moreover, phagocyte depletion did not reduce the numbers of bone marrow osteoblasts or nestin$^+$ MSCs. In contrast, Winkler et al. [114] observed reduced osteoblast numbers and decreased osteoblastic expression of CXCL12, Ang-1, and SCF following phagocyte depletion. Although more work is required to better define the mechanism(s) involved in phagocyte depletion-mediated HSPC mobilization, the data strongly suggest that bone marrow monocytes/macrophages produce trophic factors that are required for nestin$^+$ MSC and osteoblast maintenance and HSPC retention.

Stem cell mobilization

Clinically available mobilizing agents

Hematopoietic stem cell mobilization has been shown to be induced clinically or experimentally in animal models by a wide variety of molecules: cytokines such as G-CSF, granulocyte–macrophage colony-stimulating factor (GM-CSF), stem cell factor (SCF), and Flt3 ligand; chemokines like interleukin (IL)-8, Mip-1α, Groβ, or SDF-1; small molecule inhibitors and CXCR4/CXCL12 and VLA-4/VCAM-1 axes; and the chemotherapeutic agents cyclophosphamide (Cy) and paclitaxel. These molecules differ in their kinetics of mobilization, the type of cells mobilized, and efficiency. To date, only G-CSF (filgrastim, Neupogen®, Amgen, Thousand Oaks, CA, USA), GM-CSF (sargramostim, Leukine®, Bayer Healthcare Pharmaceuticals, Seattle, WA, USA), SCF (ancestim, Stemgen®, Amgen, Thousand Oaks, CA, USA available in Canada and New Zealand only) and plerixafor (Mozobil, AMD3100, Genzyme Corporation, Cambridge, MA, USA) are approved clinically for use in stem cell mobilization [115]. In general, these mobilizing agents function by disrupting HSPC adhesion to stromal cells and/or disrupting the chemotactic gradients responsible for maintaining stem cells in the bone marrow microenvironment. In the following sections we will discuss the mechanism of action of these mobilizing agents in greater detail.

Mobilization of HSPCs with G-CSF

G-CSF is a myeloid growth factor produced by monocytes, macrophages, fibroblasts, and endothelial cells and is the most commonly used mobilizing agent for HCT (clinical studies have been reviewed elsewhere in this text). Although the mechanisms by which G-CSF induces HSPC mobilization are not fully understood, there is evidence that at least three general mechanisms of mobilization are involved: activation of proteases, attenuation of adhesion molecule function, and disruption of CXCL12/CXCR4 signaling (reviewed in [116,117]).

CXCR4/CXCL12 axis and G-CSF mobilization

CXCR4/CXCL12-axis dysfunction in WHIM syndrome

Additional genetic evidence for the critical role that CXCR4 plays in leukocyte trafficking has been obtained from patients with the genetic immunodeficiency syndrome WHIM (warts, hypogammaglobulinemia, infections, myelokathexis). Although the majority of patients with WHIM syndrome have autosomal dominant C-terminal truncation mutations of 10-19 amino acids in CXCR4 [118–120], a single missense, non-truncating, gain-of-function mutation in the C-terminal tail of CXCR4 (E343K) was recently associated with the disease [121]. These mutations in the intracellular C-terminal tail of CXCR4 prevent internalization and desensitization in response to CXCL12 [118,119,121,122]. Some functional consequences of dysregulated CXCR4 signaling in WHIM syndrome is the failure of mature neutrophils to exit the bone marrow (myelokathexis) resulting in peripheral neutropenia, defects in B-cell development, reduced immune function, and other similarities to murine CXCL12 and CXCR4 knockout mice [121,123,124]. Interestingly, administration of the CXCR4 antagonist plerixafor appears to be a safe and effective strategy to correct this leukopenia, the major cellular mechanism of immunodeficiency in the disease [125].

Multiple lines of evidence suggest that G-CSF mediates mobilization through suppression of the CXCL12/CXCR4 axis. Although G-CSF administration results in an early, transient increase in CXCL12 production [126] prolonged treatment induces a progressive decrease in CXCL12 mRNA [68] in the BM with a concurrent drop in CXCL12 protein [68,126,127]. In fact, BM CXCL12 levels are inversely correlated with the magnitude of HSPC mobilization, with low levels of CXCL12 mRNA or protein correlating with maximal mobilization [51,68,126]. The expression of CXCR4 on HSPCs is dynamic and G-CSF treatment is associated with decreased cell-surface expression of CXCR4 on mobilized cells [127,128]. One potential mechanism for the decreased CXCL12 expression following G-CSF treatment, as discussed earlier, is that G-CSF treatment is associated with a marked suppression of osteoblasts [51,55,68,129], which are an important source of CXCL12 in the bone marrow. Importantly, no G-CSF-mediated mobilization is observed following neutralization of CXCR4 with monoclonal antibodies [126] or in CXCR4$^{-/-}$ BM chimeras [55]. These data indicate that disruption of the CXCR4/CXCL12 axis plays a dominant role in HSPC mobilization by G-CSF.

Degradation of CXCL12 may also be involved in the mobilization of HSPCs by G-CSF. Studies have shown that CXCL12 is rapidly processed in vivo at both the N- and C-termini [130]. The enzymes responsible for N-terminal truncation of CXCL12 include CD26 (DPP4, dipeptidylpeptidase IV), metalloproteases, leukocyte elastase and cathepsin G, and C-terminal truncation proceeds via carboxypetidase M and cathepsins B, K, L, and X [131–137]. These truncations at both the N- and the C-termini of CXCL12 have been shown to modify its affinity for CXCR4 and its biologic activity in in vitro assays. Interestingly, G-CSF-induced HSPC mobilization is defective in CD26-deficient mice or in wild-type mice treated with a specific CD26 inhibitor [138,139]. Furthermore, expression of CD26 on human CD34$^+$CD38$^-$ HSPCs is enhanced upon treatment with G-CSF, resulting in a decreased chemotactic response to CXCL12 [140]. These data suggest that CD26 is an essential component of G-CSF-induced HSPC mobilization.

G-CSF-mediated mobilization via activation of proteases

G-CSF is known to induce neutrophil proliferation, activation, and degranulation [141,142], resulting in the release of serine and metallo-proteases such as MMP-9, cathepsin G, and neutrophil elastase [143]. HSPCs themselves contribute to the development of a proteolytic microenvironment by secreting MMP-2 and MMP-9 [144], upregulating metalloproteinase membrane type 1-metalloprotease (MT1-MMP), and suppressing expression of the MT1-MMP inhibitor reversion-inducing cysteine-rich protein with Kazal motifs (RECK) after G-CSF treatment. G-CSF also directly stimulates BM MSCs to induce MMP-2 synthesis and its activation at the membrane. Since the accumulation of these proteases in the BM microenvironment and on HSPCs mirrors the kinetics of HSPC mobilization, it was suggested that these proteases promote mobilization by cleaving a variety of HSPC supporting molecules including SCF [76], VCAM-1 [145], CXCL12 [133,134,138,146,147], CXCR4 [127], and CD44 [148]. Moreover, expression of serpin1 and serpin3, naturally occurring inhibitors of these proteases, is markedly reduced after G-CSF treatment, thus making the marrow environment even more proteolytic [149,150]. Although the role these serpins play in G-CSF-mediated mobilization has not been evaluated, administration of serpin1a inhibits IL-8-mediated mobilization [150].

The role of proteases in G-CSF-mediated mobilization is controversial. Depletion of neutrophils in mice using an antibody against GR1 (Ly6C/G) results in reduced mobilization by G-CSF [151], IL-8 [77], and Groβ [151]. Furthermore, anti-MMP-9 antibodies inhibit mobilization by IL-8 or Groβ by 90% and mobilization by G-CSF by 40% in mice [78,151]. In agreement with these data, G-CSF-induced mobilization of HSPCs is impaired in MMP-9 [76] and MT1-MMP [148]-deficient mice and augmented by co-administration of poly-(1,6)-β-d-glucopyranosyl-(1,3)-β-d-glucopyranose (PGG), a compound that promotes MMP-9 release [152]. Similarly, inhibitors to MMP-9 or neutrophil elastase reduce G-CSF-mediated mobilization [126,151]. However, the role proteases play in G-CSF-mediated HSPC mobilization was brought into question when multiple groups were unable to reproduce the mobilization defect in MMP-9-deficient mice [153–156]. Furthermore, mice deficient in combinations of neutrophil elastase, cathepsin G, and MMP-9 display normal G-CSF-induced HSC mobilization even in the presence of a broad-spectrum metalloproteinase inhibitor [153]. Though the reason for the discrepancy between these studies is unknown, it is possible that the different genetic strains of mice used may account for the observed differences. Overall, the data suggest that while not absolutely required, proteases may augment HSC mobilization by G-CSF.

Disruption of VCAM-1/VLA-4 axis in G-CSF mobilization

The expression of VLA-4 on human CD34$^+$ HSPCs is known to be increased by IL-3 and SCF [157] and decreased by G-CSF [157–162]. Furthermore, G-CSF has been reported to induce proteases that cleave VCAM-1 [143,145]. In comparison to BM CD34$^+$ cells at steady-state, G-CSF-mobilized CD34$^+$ HSPCs exhibit reduced VLA-4 affinity and avidity for a soluble VCAM-1-Ig fusion protein [162]. Furthermore, Lichterfeld et al. [162] reported that the number of circulating CD34$^+$ cells following G-CSF administration is inversely related to the number of CD34$^+$/VCAM-1-Ig$^+$ cells in the periphery. These data suggest that a low activation state of VLA-4 on CD34$^+$ cells during G-CSF mobilization is associated with a higher number of circulating HSPCs. Therefore, both reduced VLA-4-expression and reduced VLA-4 avidity are associated with mobilization of human CD34$^+$ HSPCs by G-CSF.

c-Kit/SCF axis in G-CSF mobilization

The involvement of the c-kit/SCF axis in G-CSF-mediated mobilization is controversial. In support of a role, it is known that G-CSF promotes the production of proteases that cleave c-kit/SCF [76,146], releasing both as soluble forms. Consistent with this observation, G-CSF-mobilized HSPCs express lower levels of c-kit than BM resident HSPC [163] and serum-soluble c-kit levels exhibit a positive correlation with CD34$^+$ HSPC yield [164]. Furthermore, disruption of the c-kit/SCF axis with soluble c-kit [165] enhances mobilization by G-CSF. However, in conflict with a role in G-CSF-mediated mobilization, W/W^v mice with deficient c-kit signaling exhibit a 50% reduction in HSPC mobilization compared to controls following G-CSF treatment [166,167]. Furthermore, mice deficient in the protease matrix metalloproteinase 9 (MMP-9), which is believed to mediate SCF cleavage, mobilize normally in response to G-CSF in multiple strains of mice [153–155]. Finally, stimulation of c-kit signaling by administration of SCF during G-CSF treatment synergistically increases the number of mobilized HSPCs [168–172]. Despite the efficacy of SCF in enhancing G-CSF mobilization, its use is hindered by the infrequent occurrence of severe anaphylactoid reactions [173]. Although approved for use in Canada and New Zealand, SCF is not currently available in the United States, and it is seldom used in Europe because of the relatively high risk of side effects.

HGF/c-Met axis in G-CSF mobilization

Hepatocyte growth factor (HGF) is a heterodimeric molecule composed of an alpha and beta chain and has been reported to play critical roles in proliferation, migration, invasion, tumor angiogenesis, and lymphangiogenesis [174,175]. The various biologic activities of HGF are mediated via the c-met proto-oncogene receptor, c-Met tyrosine kinase, which is expressed on a variety of cell types and is upregulated by numerous inflammatory molecules [176,177]. Both HSPC and serum levels of HGF are elevated in G-CSF-mobilized donors [178–180] and G-CSF upregulates c-met expression in human CD34$^+$ and mouse HSPCs [179,180]. Direct injection of HGF to mice induces HSPC mobilization [72,180,181] and administration of c-Met neutralizing antibodies or the c-met inhibitor PHA-665752 inhibits G-CSF-mediated mobilization [180]. The main regulator of c-Met transcription, HIFIα, is upregulated by G-CSF treatment [182]. The HCF/c-Met axis may promote mobilization by activating mammalian target of rapamycin (mTOR) and increasing reactive oxygen species (ROS) production in HSPCs as well as stimulating the secretion of MMP-9 and surface expression of MT1-MMP on BM MNCs [179,180]. In agreement with these data, inhibition of mTOR with rapamycin [148,180] or ROS with *N*-acetyl-*L*-cysteine [180] reduced G-CSF-mediated mobilization. Furthermore, knockout of the thioredoxin-interacting protein, a mediator of oxidative stress, results in increased G-CSF-mediated mobilization, further suggesting a role for ROS in HSPC mobilization [183].

EGF/EGFR axis in G-CSF mobilization

Similar to humans, there is a wide variation in the magnitude of HSPC mobilization by different inbred strains of mice in response to G-CSF. Following G-CSF treatment for 5 days, Roberts et al. [167] observed a 10-fold range in the number of circulating progenitor cells between different inbred strains of mice, with the mobilization efficacy roughly aligning in the following order: DBA > 129Sv > BALB/c = SJL > C57Bl/6 = C3H/He. Using a forward genetic approach and a congenic mouse model, Geiger et al. [184] identified linkage between a locus on chromosome 11 and the magnitude of HSPC mobilization by G-CSF. Subsequent gene mapping studies by the same group identified that the gene for epidermal growth factor receptor (EGFR) on chromosome 11 negatively influences HSPC mobilization in response to GCSF [185]. Interestingly, G-CSF-induced HSPC mobilization was enhanced in EGFR signaling-deficient mice or in wild-type mice treated with the EGFR inhibitor erlotinib. Moreover, increased mobilization due to suppression of EGFR activity correlated with reduced activity of cell division control protein-42 (Cdc42), and mice deficient in Cdc42 exhibited enhanced G-CSF-induced mobilization [185]. These data suggest that EGF-EGFR signaling modulates G-CSF-mediated mobilization through modulation of Cdc42 activity.

Cellular mediators of G-CSF mobilization

G-CSF mobilizes HSPCs through a hematopoietic intermediate

G-CSF functions via the G-CSF receptor (G-CSFR), which is a member of the type I cytokine receptor family and expressed on both hematopoietic and non-hematopoietic cells. Mice lacking the G-CSFR (*Csf3r*$^{-/-}$) have reduced numbers of HSPCs in the bone marrow and are unresponsive to G-CSF stimulation [186]. Mobilization of HSPCs by G-CSF requires expression of G-CSFR in hematopoietic cells but not stromal cells [187]. Surprisingly, however, G-CSFR expression in HSPCs is not required for mobilization [187]. This observation suggests that G-CSF induces HSPC mobilization indirectly by acting on a hematopoietic intermediary that generates trans-acting signal(s) that lead to HSPC mobilization.

The specific hematopoietic cell type(s) that mediate HSPC mobilization by G-CSF is still under investigation. The G-CSFR is expressed on a broad range of hematopoietic cells, with high expression levels on mature and immature neutrophils, and intermediate levels on monocytes/macrophages, HSPCs, and a subset of B lymphocytes and NK cells [188]. Recent work by Christopher et al. [83] demonstrated that G-CSF signaling in a CD68$^+$ monocyte/macrophage lineage cell within the bone marrow initiates the HSPC mobilization cascade. In these studies, mice expressing the G-CSFR exclusively on CD68$^+$ monocytic cells (CD68:G-CSFR) restored HSPC to G-CSFR knockout mice, suggesting that activation of the G-CSFR in the monocytic lineage is sufficient to mediate HSPC mobilization. Moreover, G-CSF decreased the absolute numbers of monocytes in the bone marrow of both CD68:G-CSFR and wild-type mice. This observation agrees with the studies discussed earlier by Chow et al. [82] and Winkler et al. [114] showing that monocyte ablation induces HSPC mobilization. Taken together, these studies suggest that monocytic cells produce currently unidentified factors that support the retention of HSPCs in the bone marrow. Furthermore, G-CSF signaling in monocytes suppresses these signals and results in the mobilization of HSPCs.

The exact monocytic cell subset that mediates HSPC mobilization by G-CSF remains unknown. The CD68 transgene used by Christopher et al. [83] directs G-CSFR expression to at least four distinct monocytic cell populations: inflammatory monocytes/macrophages, resident monocytes/macrophages, myeloid dendritic cells, and osteoclasts. Therefore, all four of these cell populations are candidates to mediate HSPC mobilization by G-CSF. The role of osteoclasts in HSPC mobilization is controversial. Kollet et al. [72] found that activation of osteoclasts by administration of RANK ligand was associated with moderate HSPC mobilization and inhibition of osteoclasts, either genetically by deleting PTPε or pharmacologically via calcitonin administration, reduced G-CSF-mediated HSPC mobilization. In contrast, studies by others suggest that osteoclasts inhibit mobilization, as mice treated with pamidronate, an osteoclast-inhibiting bisphosphonate, promote mobilization by G-CSF [114,189]. Furthermore, Winkler et al. [114] reported no alterations in the number of osteoclasts on endosteal surfaces during G-CSF administration. Since ablation of CD169$^+$ macrophages resulted in HSPC mobilization [82], CD169$^+$ macrophages may be the monocytic cell population that mediates HSPC mobilization.

G-CSF suppresses osteoblast lineage cells in the bone marrow

Studies suggest that bone marrow macrophages are anatomically juxtaposed with endosteal osteoblasts and produce factors that support the growth and/or survival of osteoblasts [82,83,114,190]. Following initiation of G-CSF treatment, the number of inflammatory and resident monocytes/macrophages in the bone marrow decreases and reaches a nadir at 3 days of G-CSF treatment, a time point at which osteoblast suppression first becomes evident [83,129]. Indeed, G-CSF administration leads to a selective reduction in the number of mature endosteal and trabecular osteoblasts that is secondary to both an increase in osteoblast apoptosis and inhibition of osteoblast differentiation [51,55,68,114,129,191]. The fact that osteoblasts do not express G-CSFR supports the concept that G-CSF-mediated osteoblast suppression is at least partially mediated by cytokine-induced monocyte/macrophage depletion. Moreover, CXCL12, SCF, and Ang-1 expression in osteoblasts is decreased after G-CSF treatment. Osteoblast suppression is a common feature of cytokine-mediated mobilization, as both Flt3L and SCF induce similar alterations in osteoblast lineage cells [55]. However, the factors generated by bone marrow macrophages that regulate CXCL12 production by bone marrow osteoblasts or stromal cells have not, as yet, been identified.

G-CSF mobilizes HSPCs through the sympathetic nervous system

Since the magnitude of HSPC mobilization by monocyte/macrophage ablation is at least twofold less than that achieved after G-CSF administration [82,114], G-CSF must elicit HSPC mobilization via additional mechanisms. The sympathetic nervous system (SNS) is involved in both the physiologic and enforced egress of HSPC from the BM. Recent studies have shown that the G-CSFR is expressed by peripheral sympathetic neurons [58] as well as neurons in the central nervous system [192]. Although BM stroma do not express the G-CSFR, nestin$^+$ MSCs express both β_2- and β_3-adrenergic receptors and mediate HSPC release from the BM in response to variations in SNS tone [52]. In contrast, osteoblasts express only the β_2 receptor and regulate their own growth, as well as osteoclast activity, in response to SNS signaling [193].

Upon binding its receptor on neurons, G-CSF enhances the sympathetic tone by altering the ability of the sympathetic neurons to take up norepinephrine, thereby increasing catecholamines available to target cells within the BM niche [59]. Katayama et al. [51] showed that G-CSF-mediated HSPC mobilization is reduced in chemically sympathectomized mice, mice treated with the β-blocker propranolol, and in dopamine β-hydoxylase (Dbh; enzyme that converts dopamine into norepinephrine)-deficient mice. Treatment of Dbh knockout mice with the β_2-adrenergic agonist clenbuterol rescued in part the G-CSF mobilization defect in $Dbh^{-/-}$ mice and enhanced mobilization in $Dbh^{+/-}$ controls [51]. This rescue of HSPC mobilization by clenbuterol in $Dbh^{-/-}$ mice, as well as mobilization of wild-type mice with G-CSF, was associated with a flattening of the bone lining osteoblasts [51]. Since osteoblasts do not express G-CSFR [51,194], this atrophic appearance and stiffening of the osteoblasts was likely mediated by β_2-adrenergic signaling. Additional unrelated studies with G-CSF and clenbuterol showed that the vitamin D receptor (VDR) is a critical mediator of neuronal control in the BM niche. Here, Kawamori et al. [191] found that VDR-deficient mice exhibit a severe impairment in G-CSF-mediated osteoblast suppression and stem cell mobilization. Additional mechanistic studies revealed that the suppression of osteoblastic activity is dependent upon VDR upregulation in osteoblasts by SNS-mediated β_2-adrenergic signaling [191]. Taken together, these data suggest that G-CSF-mediated β_2-adrenergic signaling promotes HSPC mobilization through VDR-mediated suppression of bone lining osteoblasts and a decrease in BM CXCL12 levels.

There is also evidence supporting a role for β_3-adrenergic signaling in G-CSF-mediated HSPC mobilization. Treatment of $nestin^+$ MSCs with a β_3-adrenergic receptor agonist induces downregulation of CXCL12, SCF, angiopoietin-1 (Ang-1), and VCAM-1 in a manner similar to G-CSF. Related to this observation, Ferraro et al. [57] found that treatment of diabetic mice with G-CSF resulted in an expected loss of osteoblasts and downregulation of CXCL12 in osteoblasts, but no change in the expression of CXCL12 by $nestin^+$ MSCs, resulting in a dramatic reduction in G-CSF-mediated HSPC mobilization. Additional studies demonstrated that altered G-CSF-induced mobilization in diabetic mice was due to a defect in the activation of the sympathetic nervous system. This defect resulted in a functional blockade of G-CSF-induced downregulation of CXCL12 in $nestin^+$ MSCs and was abrogated through the administration of a β_3-adrenergic receptor antagonist [57]. Finally, Mendez-Ferrer et al. [195] recently examined G-CSF-induced HSPC mobilization in mice deficient in either β_2-adrenergic receptor, β_3-adrenergic receptor, or both β_2- and β_3-adrenergic receptors. Animals lacking the β_3-adrenergic receptor showed no defect in mobilization while mice lacking the β_2-adrenergic receptor showed a trend towards reduced HSPC egress. However, mice lacking both the β_2- and β_3-adrenergic receptors exhibited a significant (50%) reduction in HSPC mobilization, suggesting cooperation between the two signaling pathways following G-CSF administration. β_2- and β_3-adrenergic receptor deficiency does not abrogate HSPC mobilization induced by macrophage depletion with clodronate-containing liposomes. These data further illustrate that multiple pathways are involved in G-CSF-mediated mobilization.

G-CSF-mediated signaling through the sympathetic nervous system also has direct effects on HPSCs. Although β_3-adrenergic receptor expression is restricted to the stromal compartment, β_2-adrenergic receptors are expressed in both the stromal and hematopoietic compartments [196], including mouse [197] and human [198] HSPCs. β_2-adrenergic receptor expression is highest on the more primitive human $CD34^+CD38^-$ cell subset and is upregulated on all human $CD34^+$ HSPCs following G-CSF administration [198]. This increase in β_2-adrenergic receptor expression is associated with an increased response to neurotransmitters, leading to enhanced proliferation and motility of human $CD34^+$ progenitors, repopulation of the BM of immunodeficient mice and their egress to the circulation [198]. Since norephinephrine treatment of mice has also been shown to increase CXCR4 expression [199], adrenergic signaling may directly affect the CXCR4/CXCL12 axis in the BM niche.

In addition to contributing to HSPC mobilization following G-CSF administration, the sympathetic nervous system also regulates physiologic HSPC trafficking via a circadian rhythm. Studies by Frenette and colleagues demonstrated that under homeostasis, HSPC egress from the BM is orchestrated by rhythmic β_3-adrenergic signals delivered by the sympathetic nervous system that regulate norephinephrine release, CXCL12 production by stromal cells, and CXCR4 expression on HSPCs [50,52,200–202]. The lowest CXCL12 expression levels in the murine BM coincide with the peak of circulating HSPCs approximately 5 hours after the onset of light and the highest BM CXCL12 levels, which occur 8 hours later (1 hour after removal of light), match the lowest numbers of peripheral HSPCs. This sympathetic nerve regulation of HSPC egress is reportedly mediated indirectly by $nestin^+$ MSCs, which express less CXCL12, as well as SCF, Ang-1, and VCAM-1, following stimulation with a β_3-adrenergic receptor agonist [50]. Interestingly, the pattern of circadian HSPC mobilization in humans is opposite to that observed in mice, with maximal egress of human HSPCs occurring in the evening [203].

Mobilization by both G-CSF and AMD3100 is affected by the circadian oscillations of HSPC trafficking. In mice, significantly more leukocytes, CFU-C and LSK cells are recovered after G-CSF or AMD3100 administration when blood collection occurs at the peak circadian time [203,204]. This can be quantitated as a doubling of CFU-C and LSK in mice at steady state and a 1.5 to twofold increase in response to G-CSF or AMD3100, respectively. In healthy humans the difference in circulating CD34/mL blood can be as great as threefold (range 1.05–3) when examined at peak circadian time (evening) compared to morning [203]. Likewise, greater numbers of human $CD34^+$ HSPCs are collected after G-CSF treatment when apheresis procedures are started in the afternoon (closer to peak circadian time) compared to the morning [203]. These findings suggest that simple adjustments in timing of stem cell harvest may result in higher yields of $CD34^+$ HSPCs.

HSPC mobilization via pharmacologic disruption of the CXCR4/CXCL12 axis

The data obtained from CXCR4-deficient mice and WHIM patients support a model in which CXCL12 signaling through CXCR4 provides a key retention signal for HSPCs in the bone marrow. Furthermore, multiple preclinical and clinical studies have demonstrated that pharmacologic disruption of the CXCL12/CXCR4 axis using various CXCR4 modulators, including small molecule peptide and non-peptide antagonists, neutralizing antibodies to CXCR4, and modified agonists and antagonists for CXCL12 induce HSPC mobilization in a target-dependent manner [205,206]. In the following sections we will discuss some of these different types of CXCR inhibitors in greater detail.

Mobilization of HSPCs with the CXCR4 antagonist plerixafor

The observation that a single injection of plerixafor can synergize with multiple injections of G-CSF indicates that the mechanisms involved in G-CSF and plerixafor HSPC mobilization are not completely overlapping [207–209]. Given that many of the mechanisms of G-CSF-induced HSPC mobilization discussed earlier involve disruption of the CXCR4/CXCL12 axis, the synergism between G-CSF and plerixafor is surprising. One potential explanation is that pharmacologic inhibition of CXCR4 by plerixafor more effectively inhibits the CXCR4/CXCL12 axis and results in increased HSPC mobilization in vivo. In support of this explanation, Chow et al. [82] recently showed that mimicking one effect of G-CSF administration, in vivo phagocyte depletion, prior to plerixafor treatment, induced a twofold increase in the magnitude of HSPC mobilization by the drug. Furthermore, plerixafor mobilizes HSPCs expressing higher levels of CXCR4 both before and during G-CSF administration [210–214]. An alternative untested explanation is that G-CSF and plerixafor mobilize HSPCs from different niches within the bone marrow environment. In this regard, putative HSPCs have been found near the endosteum lined by osteoblasts (endosteal niche) and in association with sinusoidal endothelium (perivascular niche) [30,215].

Plerixafor and G-CSF mobilize phenotypically different CD34$^+$ cell subsets

HSPCs mobilized with plerixafor are intrinsically different compared to their counterparts mobilized with G-CSF [216]. For example, HSPCs mobilized with plerixafor contain a higher proportion of CD34$^+$ cells in G_1 phase of the cell cycle and a higher proportion of the more primitive CD34$^+$CD38$^-$ subset than G-CSF [211,212,217]. HSPCs mobilized with plerixafor and G-CSF exhibit increased surface expression of CXCR4 and VLA-4 (CD49d) which likely contribute to enhanced engraftment [210–212,218]. Furthermore, the gene expression profiles differ between CD34$^+$ HSPCs mobilized by plerixafor plus G-CSF and those mobilized by G-CSF alone, with plerixafor plus G-CSF associated with decreased expression of proapoptotic genes and increased expression of genes for CXCR4, cell cycle promotion, cell adhesion, cell motility, oxygen transport, DNA repair, and antiapoptosis [210]. Additional global gene and microRNA expression analysis on rhesus macaque CD34$^+$ HSPCs revealed that G-CSF mobilizes a greater proportion of HSPCs that are committed toward myeloid differentiation, whereas those mobilized by plerixafor are more likely to be committed toward B, T, and mast cells [219]. Taken together, these data clearly indicate that the composition of G-CSF and plerixafor-mobilized grafts are significantly different. What impact these different types of grafts have on the engraftment and function of HSPCs after HCT remains largely unknown.

Alternative agents to disrupt the CXCR4/CXCL12 axis

Despite the efficacy of current mobilization regimens, there is still a significant portion of patients who fail to mobilize an adequate number of HSPCs to proceed to transplantation [220]. For example, nearly one third of healthy donors mobilized with plerixafor alone require more than one apheresis to obtain the minimal number of CD34$^+$ HSPCs ($\geq 2.0 \times 10^6$ CD34$^+$ cells/kg) necessary for transplantation [221]. In addition, CXCR4 inhibitors may function as therapeutic agents in cancer therapy as antitumor, antimetastatic and/or chemosensitization agents [206,222–225], as well as in inflammation and tissue repair [226–233]. Therefore, efforts to discover and develop more potent and orally available inhibitors of the CXCR4/CXCL12 axis continue.

Mobilization of HSPCs using CXCR4 antagonists

A number of lead drug candidates that target the CXCR4/CXCL12 axis have recently been developed. These drugs fall into peptide and non-peptide CXCR4 antagonists and CXCR4 antibodies. The prototypical small peptide antagonist, T140 [234], was derived from naturally occurring peptides that had anti-HIV-1 activity. Stable derivatives based on T140 are in clinical development [235,238]. Furthest in development is POL6326 (Polyphor), a selective and reversible CXCR4 inhibitor belonging to a novel drug class based on β-hairpin protein epitope mimetics. A single injection of POL6326 to mice produces an 11–12-fold increase in circulating progenitor cells with a peak at 2–4 hours post-dosing [235]. POL6326 is currently being tested in phase I/II studies for HSPC mobilization in autologous and allogeneic HCT. Non-peptide molecules derived from the prototypical antagonist, plerixafor, have also been described and are in clinical development [206,236,237]. Finally, anti-CXCR4 antibodies [238,239] have been developed but fail to mobilize sufficient CD34$^+$ HSPCs but are in development to alter tumor stromal interactions [240].

Mobilization of HSPCs using CXCR4 agonists

CXCR4 pepducins

Pepducins are highly stable synthetic lipopeptides that are composed of the amino acid sequence of an intracellular loop of the target G-protein coupled receptor coupled to a lipid tether. The pepducins PZ-218, PX-305, and ATI-2341 (Anchor Therapeutics, Cambridge, MA, USA) are based on the first intracellular loop of CXCR4, while PZ-210 targets the third intracellular loop [241–243]. Like CXCL12, these pepducins activate CXCR4-dependent signaling pathways, induce receptor internalization, and promote both in vitro and in vivo chemotaxis. Interestingly, ATI-2341 also acts as a functional antagonist to mobilize HSPCs from the BM niche in both mice and non-human primates [242].

Small peptide analogs of SDF mobilize HSPCs

A large number of CXCL12 small peptide analogs have been designed as CXCR4 agonists and antagonists [244]. In general, CXCR4 agonists induce HSPC mobilization by downregulating cell surface expression of CXCR4 and/or collapsing the CXCL12 gradient between the BM niche and peripheral circulation. Studies have shown that disruption of the CXCL12 gradient between the bone marrow and the peripheral blood by the administration of sulfated polysaccharides [245] or adenovirus expressing CXCL12 [246] results in an increase in circulating CXCL12 and HSPC mobilization. Interestingly, plerixafor-mediated HSPC mobilization was recently shown to be associated with increased CXCL12 plasma levels and could be inhibited by anti-CXCL12 antibodies [247]. This observation suggests that in addition to acting as a CXCR4 antagonist, plerixafor may also promote HSPC mobilization by reversing the CXCL12 gradient between the BM niche and peripheral circulation. CTCE-0021 and CTCE-0214 are small cyclized CXCR4 agonist peptides that were developed by linking amino acids 1–14 and 55–67 of CXCL12 with four glycine residues [248,249]. CTCE-0214 differs from CTCE-0021 by the substitution of two amino acids to improve plasma stability. Both analogs rapidly mobilize HSPCs in mice through CXCR4 receptor desensitization and/or downregulation of surface CXCR4 expression [248,249].

NOX-A12 (NOXXON Pharma, Berlin, Germany) is an L-enantiomeric RNA oligonucleotide (Spiegelmer) that binds and neutralizes

CXCL12 [250]. Spiegelmers are mirror-image nuclease-resistant ribonucleotides that bind and inhibit target molecules in a manner conceptually similar to antibodies [251,252]. Preclinical studies in the mouse demonstrated that the 45 nucleotide long NOX-A12 increases the plasma level of CXCL12. Results from a clinical trial comparing the mobilization of HSPCs by NOX-A12 alone with that obtained in combination with G-CSF have not been reported.

HSPC mobilizing agents that target VLA-4

Mobilization of HSPCs by anti-α_4 integrin antibodies

Separate studies have shown that treatment of mice, primates, and humans with antibodies to VLA-4 increases the number of circulating HSPCs. Blockade of α_4 in mice [110,111,166,253–255] and non-human primates [253,255,256] induces rapid (<8 hours) and prolonged (>10 days) mobilization of HSPCs with long-term repopulating ability. Interestingly, a functional kit receptor is required for HSPC mobilization by an anti-α_4 integrin antibody [166] and either additive or synergistic HSPC mobilization was observed when the antibody was combined with G-CSF [255,256], plerixafor [253], SCF [255] and/or Flt3-ligand [255]. This enhanced mobilization of HSPCs following combination therapy is likely mediated by the disruption of the CXCR4/CXCL12 axis [55,254].

Elevated circulating levels of HSPCs are also observed following administration of an anti-VLA-4 antibody to patients with multiple sclerosis (MS). Natalizumab (Tysabri; Biogen Idec, Cambridge, MA) is a recombinant humanized neutralizing IgG4 monoclonal antibody against the α_4 subunit of VLA-4 that is approved for the treatment of relapsing–remitting multiple sclerosis. Similar to mice and non-human primates following anti-α_4 integrin antibody administration, MS patients treated with natalizumab display a rapid and sustained increase in circulating CD34$^+$ HSPCs [257–259]. The number of circulating CD34$^+$ cells/μL blood increased three- to fivefold during the first 72 hours after treatment and remained elevated at these levels (8–10 CD34$^+$ cells/μL) for at least a month after antibody treatment [257–259]. This number of circulating CD34$^+$ cells in natalizumab-treated MS patients is approximately one sixth and one third of those observed following treatment of healthy donors with G-CSF and plerixafor, respectively [220,221,257–259]. Functional and phenotyping studies on natalizumab-mobilized CD34$^+$ HSPCs indicated that they were primarily quiescent (>90% in G0), failed to transmigrate towards CXCL12, and belonged to the subset of more committed progenitors co-expressing CD38 [257–259].

Although natalizumab has shown clinical efficacy and provided validation for the involvement of the α_4 integrin pathway in autoimmune and inflammatory conditions, its use as a clinical stem cell mobilizing agent in normal healthy donors is not justifiable because of its prolonged immune-modulating effects and association with an increased risk for progressive multifocal leucoencephalopathy.

Clinical trials with small molecule α_4 integrin antagonists

Because natalizumab has shown clinical efficacy in the treatment of MS and Crohn's disease, the development of small molecule VLA-4 antagonists is seen as a promising pharmaceutical approach to a novel class of therapeutic agents [260]. Early studies with the α_4 integrin antagonists suffered from poor bioavailability and a short half-life. More recent trials with orally active new generation antagonists like SB-683699/Firategrast [261] and AJM-300 [262] suggest that these compounds exhibit more favorable pharmacologic properties. However, there is no published information on the effects of these α_4 integrin antagonists on CD34$^+$ HSPC mobilization.

Mobilization of murine HSPCs by small molecule antagonists of VLA-4

BIO5192 is a potent (K_d of <10 pM) and highly selective small molecule inhibitor of both the inactivated and activated forms of human, mouse, and rat $\alpha_4\beta_1$ integrin [263]. Blockade of VLA-4 with a single injection of BIO5192 alone resulted in a 30-fold increase in mobilization of murine CFU-Cs over basal levels [264]. Peripheral blood HSPC levels peaked within 1 hour after BIO5192 administration and returned to baseline by 6 hours. Interestingly, an additive effect on HSPC mobilization was observed when BIO5192 was combined with plerixafor (threefold compared to plerixafor alone), G-CSF (fivefold compared to G-CSF alone), or their combination (17-fold compared to G-CSF alone). These data provided the first evidence for the utility of small molecule inhibitors of VLA-4 either alone or in combination with G-CSF or plerixafor for mobilization of HSPCs.

To gain a better understand of the relationship between CXCR4 and VLA-4 in HSPC mobilization, Christopher et al. [55] generated CXCR4$^{-/-}$ bone marrow chimeras by transplanting CXCR4$^{-/-}$ fetal liver cells into lethally irradiated wild-type recipient mice. Following hematopoietic reconstitution, the CXCR4$^{-/-}$ chimeras were used to investigate the function of different mobilization agents in the absence of CXCR4/CXCL12 signaling. Surprisingly, mobilization by G-CSF or Groβ was completely abrogated in CXCR4$^{-/-}$ bone marrow chimeras [55]. In contrast, HSPC mobilization by BIO5192 was robust; exhibiting a nearly 3000-fold increase in the number of circulating CFU-Cs in the CXCR4$^{-/-}$ chimeras compared to untreated control mice. These observations suggest that α_4 integrin antagonist-induced mobilization of HSPCs occurs independently of CXCR4/CXCL12 signaling and further support the notion that CXCR4 and VLA-4 are the dominant receptors regulating HSPC migration from and retention within the bone marrow.

Other biologic factors involved in mobilization

Parathyroid hormone (PTH) and mobilization

Parathyroid hormone (PTH) is FDA-approved for treatment of osteoporosis in post-menopausal women. PTH increases the number of HSPCs by supporting the growth of osteoblasts [33]. In mice, some PTH regimens increase the number of HSPCs that can be mobilized by G-CSF [265], whereas others directly induce HSPC mobilization [266]. In a phase I trial, PTH combined with G-CSF successfully mobilized sufficient HSCs in 11 of 20 patients who failed a previous mobilization attempt [267].

Complement and mobilization

The complement system is part of the innate immune system and plays a role in mobilization of HSPCs in mice [268–273]. Complement is activated in the setting of inflammation and tissue injury such as occurs with strenuous exercise and hypoxia as well as a result of cytokine administration for stem cell mobilization. Defects in either the classical or alternative pathways of complement activation can abrogate mobilization by G-CSF, the polysaccharide zymosan, and AMD3100 [271]. G-CSF mobilization results in antibody generation that results in classical complement activation [271]. Zymosan activates complement in an antibody-independent manner, through the alternative pathway [271]. Complement C5 and its cleavage byproducts affect secretion of proteolytic enzymes that play a role in releasing HSPCs into the circulation [269,270,274]. AMD3100 directly affects neutrophil release of proteases that cleave and activate C5 [269]. This process is coupled with neutrophil egress from the marrow, which release proteases, exit the marrow first, and pave the way for HSPCs to egress from the marrow [269,274]. Recent evidence also suggests that egress of HSPCs is mediated by a sphygosine-1-phosphate (S1P) gradient that results from complement activation and interaction of the membrane attack complex with red blood cells (RBCs), a major cellular store of S1P [272]. This biology has been exploited in an attempt to improve mobilization by combining G-CSF with antagonism of the complement receptor C3aR, which results in increased mobilization of HSPCs [268]. Finally, complement C3a may directly interact with CXCL12 to enhance chemotaxis of human CD34$^+$ HSCs towards sources of CXCL12 [275].

Hypoxia, HIF-1α and mobilization

The diffusion of oxygen within the marrow is inversely related to the distance from vasculature: regions near bone have lower oxygen tension [182]. This molecular characteristic of the marrow microenvironment is altered during stem cell mobilization. Mobilization with G-CSF or cyclophosphamide results in increased regions of hypoxia in the central marrow [182]. Hypoxia can have pleotropic effects. One is induction of CXCL12 from stromal cells that under steady state maintain a gradient of increased levels near bone [89]. Another is increased HIF1α protein level by prevention of its degradation. HIF1α leads to increased vascular endothelial growth factor A (VEGF-A) production, which, as described previously, can result in protease production, increased vascular permeability and vasodilation [276]. As mentioned in the HGF/c-Met axis section above, the main regulator of c-Met transcription, HIF1α, is upregulated by G-CSF treatment [182]. In addition, the major cellular consumers of oxygen are megakaryocytes, granulocytes/monocytes, and adipocytes [182]. It is predicted that as little as three layers of monocytes/granulocyte progenitors may deplete subjacent oxygen levels. The change in oxygen tension during HSPC mobilization may account for some of the mobilization effects of cytokines such as G-CSF and GM-CSF that result in bone marrow expansion and increased progenitors but the CXCR4 antagonist plerixafor (AMD3100) seems to be less affected. Stabilizing HIF1α with FG-4497 and DMOG results in HSC quiescence and radio-protection [277] as well as synergistic mobilization when combined with G-CSF [90].

Bioactive sphingolipids and mobilization

Bioactive sphingolipids include S1P and ceramide-1-phosphate (C1P). These are ubiquitous cellular components with large stores of S1P found in RBCs. Gradients of S1P and C1P have been reported to be involved in HSC trafficking and mobilization [272,278–281]. Of the five G protein-coupled 7-transmembrane receptors for S1P, the principle receptor expressed on HSCs is S1P$_1$ [281]. S1P$_1$ receptor expression and an S1P gradient between blood and bone marrow is important for mobilization induced by CXCR4 antagonists such as plerixafor (AMD3100) [278]. Mice lacking S1P$_1$ show impaired mobilization to AMD3100 [278]. In addition, the small molecule inhibitor of S1P receptors, FYT-720, inhibits mobilization by AMD3100, while the S1P$_1$ agonist, SEW2871, enhances mobilization by AMD3100. The exact mechanism is not completely known but may be related to the gradient of S1P between peripheral blood and bone marrow that is directly correlated with CXCL12 levels [278,280]. However, plasma levels of S1P in normal human donors mobilized with AMD3100 do not correlate with mobilization of CD34$^+$ cells and levels of S1P actually decrease in plasma of mice treated with G-CSF or AMD3100 [278]. These conflicting data may be potentially reconciled by the fact that mobilization is a local event and general plasma levels of S1P may not reflect changes in the microenvironment. In fact this is a well-described phenomenon that occurs with the chemo-attractant, CXCL12, where plasma levels remain unchanged but bone marrow levels are reduced after G-CSF mobilization [127]. As mentioned earlier the interaction of complement and MAC may release S1P from intracellular stores in RBCs to facilitate mobilization by G-CSF [84] but the direct evidence for S1P/S1P$_1$ axis playing a role in G-CSF-mediated mobilization is not clear with two independent groups demonstrating different results in mice [278,280]. Potential ways that this pathway can be exploited using S1P receptor agonists may be explored in the future.

Conclusion

In conclusion, the biology of stem cell mobilization is a complex interplay between stem cell and the many bone marrow niche components. A number of cellular and non-cellular factors acting through direct structural or physical ways or indirect through humoral, paracrine, metabolic, or neurologic ways regulate the bone marrow environment and are targets for inducing HSPC mobilization. Novel agents targeting critical pathways of HSC retention in the niche are actively being developed for clinical applications.

CHAPTER 6

Expansion of Human Hematopoietic Stem Cells

Colleen Delaney
Fred Hutchinson Cancer Research Center, Seattle, WA, USA

Introduction

Hematopoietic stem cells (HSCs) are useful in a variety of clinical settings and are routinely available in sufficient numbers from a variety of sources, including bone marrow and mobilized peripheral blood. However, there are instances when the number of available HSCs is insufficient for adequate and/or timely engraftment of the host. This is particularly relevant for patients undergoing cord blood transplant (CBT) who receive approximately one log less of HSPC resulting in a significant delay in hematopoietic recovery, or in the case of gene therapy, where the frequency of transduced cells is too low. One potential solution to the problem of low stem cell numbers is ex vivo proliferation of the cells prior to transplantation. Extensive research has been done to define the optimal conditions necessary for ex vivo expansion of HSCs, and various expansion techniques have been developed for this purpose [1,2]. However, while there is still a lack of convincing data that pluripotent stem cells increase in number and retain an ability to engraft and sustain long-term multilineage hematopoiesis in a myeloablated recipient following ex vivo expansion, more recent advances in the field, particularly with respect to molecular mechanisms that control HSC amplification, make this goal more realistic.

To date, substantial effort has focused on the exogenous signals that may be used to favor stem cell self-renewal versus differentiation in order to develop optimal conditions for the ex vivo expansion of HSPCs. Earlier studies evaluated using combinations of cytokines and/or bone marrow stroma and met with limited success (for more details, see reviews [1,3]). The effect of cytokines that support hematopoietic cell survival, proliferation, and differentiation has been extensively studied in vitro, but a significant role for these cytokines in enhancing self-renewal has not been shown. Consequently, a stochastic model of cellular determination has been suggested in which the fate of hematopoietic precursors is not instructed by soluble cytokines, but rather by specific interactions between stem and other cells within a particular microenvironment or "stem cell niche." These interactions are mediated by extrinsic regulators of stem cell fate and are likely to play a key role in maintaining numbers of HSC by regulating their self-renewal and differentiation, now demonstrated by the work of several groups [4–6]. Thus, more recent studies are aimed at identifying intrinsic and extrinsic factors that target the molecular pathways involved in regulation of HSC fate. Initial clinical trials using expanded HSPCs, which also mainly evaluated cytokine-driven expansion systems, did not provide evidence for stem cell expansion, although did provide evidence for the feasibility and safety of ex vivo culturing of stem cells [1]. However, as discussed later, the last decade has witnessed an increase in the number of newer generation clinical trials, primarily with ex vivo expanded CB-derived HSPC that evaluate the use of extrinsic regulators of stem cell fate and co-culture systems utilizing non-hematopoietic components (mesenchymal stromal cells) of the stem cell niche with promising results. This chapter will focus on studies of human HSC expansion for clinical applications, including studies and novel approaches in the preclinical phase of development, a discussion of technologies and assessments required to translate promising in vitro systems to the clinic, and a review of current clinical trials using expanded HSPC (Figure 6.1).

Initial attempts at ex vivo stem cell expansion for clinical application using cytokine-based expansion systems

The first report of a clinical trial using in vitro cultured hematopoietic progenitor cells appeared in 1992. Since then, a number of trials have been carried out with the primary goal of enhancing hematopoietic recovery after high-dose chemotherapy/radiation with the infusion of expanded stem cell grafts derived from bone marrow (BM), mobilized peripheral blood, or CB.

Initial preclinical studies with human BM, mPBSC, or CB-derived HSC were cytokine-based expansion systems. These studies evaluated HSC culture in the presence of various cytokine combinations and were only moderately successful demonstrating significant expansions of committed myeloid progenitor cells but only two- to fivefold net increase in long-term repopulating cells after 4 to 21 days in culture [7–10]. With the expectation that these committed progenitor cells would enhance absolute neutrophil count (ANC) recovery, cytokine-mediated ex vivo expansion methods were translated to the clinic for autologous and allogeneic uses. Studies of expanded mobilized PBPCs were all done in the autologous setting, and included only those patients with sufficient stem cell harvests to allow the use of an aliquot of the apheresis product for expansion. This excluded "poor mobilizers" who clearly stand to benefit from expansion procedures allowing them to undergo treatment with high-dose therapy. However, it is not known whether HSCs derived from such patients are equivalent to those derived from patients with adequate mobilization of HSCs. These trials, primarily in breast cancer patients, assessed enhanced short-term repopulation as a function of decreased time to neutrophil and/or platelet engraftment. With one exception, these studies were unable

Cord blood graft engineering:
Overcoming the cell–dose barrier

Increase the available cell dose for infusion

- Infusion of multiple units (UMINN – Wagner/Barker)
    - – Well established and a platform for ex vivo expansion
- Infusion of haplo or TPD cells (Fernandez, van Besien, Childs)
    - – Haplocord trials for both malignant and non-malignant dz
- Ex vivo expansion of CB stem/progenitor cells
    - – Notch (Delaney/Bernstein)
    - – MSC co-culture systems (Shpall), Mesoblast
    - – Copper chelator (Stemex®)
    - – NAM (Nicord®)
      Gamida cell
    - – Aryl hydrocarbon receptor, Novartis
    - – Preclinical – novel proteins (e.g., HOXB4, Angptl5, IGFBP2)
- Ex vivo expansion – 3D, bioreactors

Enhanced homing

- Direct intra-marrow injections (Frassoni, et al.)
- PGE2 (Zon, Cutler et al.) - FATE therapeutics
- DPPIV (Broxmeyer, et al.)
- Fucosylation (Shpall, et al.) America stem cell
- C3a priming (Brunstein, et al.)

Figure 6.1 Examples of current approaches under preclinical and clinical development

to address the expansion of long-term repopulating HSCs because patients received non-myeloablative chemotherapy and/or infusion of non-cultured cells.

Overall, although the safety and feasibility of HSC expansion approaches were demonstrated, more rapid engraftment was not observed in patients receiving reduced-intensity preparative regimens. There have, however, been suggestions of ex vivo expansion of short-term repopulating cells in patients who have received myeloablative therapy. For example, in a study by Holyoake et al. [11], the gain of short-term repopulating cells at the expense of long-term repopulating cells was suggested. In that study, mobilized PBPCs cultured ex vivo with SCF, IL-1β, IL-3, IL-6, erythropoietin, and autologous plasma for 8 days were infused in the absence of non-cultured cells into patients who had received myeloablative chemotherapy. None of the four patients showed evidence of long-term hematopoietic recovery, and all required infusions of unmanipulated cryopreserved autologous back-up mobilized PBPCs, after which full hematopoietic recovery was seen. Three patients showed initial neutrophil engraftment that was not sustained, suggesting that short-term repopulating cells may have been generated ex vivo at the expense of long-term repopulating ones, possibly by inducing their differentiation.

A shortening of the neutropenic period following high-dose chemotherapy in 21 patients with breast cancer was also shown in a study in which autologous mobilized PBPCs were cultured with SCF, G-CSF, and megakaryocyte growth and development factor for 10 days. The patients in this study were divided into two cohorts: those who received expanded cells only, and those who received both expanded and unmanipulated cells in tandem [12]. Expanded PBPCs resulted in a more rapid neutrophil engraftment ($p = 0.02$ for cohorts 1 and 2 vs. the historical controls), the best predictor of time to neutrophil engraftment was the total number of cells harvested after expansion, and patients receiving more than 4×10^7 cells/kg engrafted by day 8. Reiffers et al. also reported a decreased time to neutrophil engraftment using the same culture conditions to expand autologous mobilized PBPCs for infusion with unmanipulated cells into patients with multiple myeloma after high-dose conditioning [13].

The use of continuous perfusion methods for the expansion of BM has been evaluated in three trials utilizing the automated perfusion bioreactor system Aastrom Replicell [14–16]. Notably, these are the only trials that used BM (unselected for CD34$^+$ cells) as the source of HSC for ex vivo expansion, thereby perhaps including accessory or stromal cells of unclear significance in expansion cultures, and perhaps enhancing the engraftment ability of this expanded cell population. In these studies, breast cancer patients underwent the same conditioning regimen, and cells derived from autologous BM were placed directly into the automated perfusion bioreactor system for expansion with Flt3L, erythropoietin, and PIXY321 cytokines, as well as fetal bovine serum and horse serum. In all trials, cultures were initiated with small amounts of harvested marrow (75–100 mL).

The trials by Stiff et al. and Engelhardt et al. used expanded cells only, while Pecora et al. also infused mobilized PBPCs in low doses. Engraftment was not enhanced but did occur, suggesting the maintenance of HSCs in the bone marrow cultures, and all trials reported a correlation between the time to neutrophil and platelet engraftment with CD34$^+$Lin$^-$ cell dose/kg. Stiff et al. reported that only 2×10^5 CD34$^+$ cells/kg of the expanded cells were needed to produce optimal platelet engraftment. This cell dose was lower than the number of cells required for predictable platelet engraftment by day 28 in breast cancer patients undergoing PBPC transplantation with unmanipulated PBPCs, in which the minimal number of CD34$^+$ cells required was reported to be $2–5 \times 10^6$/kg [17].

In a trial of CBT in individuals with hematologic malignancies undergoing high-dose preparative regimens, Shpall and colleagues used a 3-cytokine cocktail (stem cell factor (SCF), thrombopoietin (TPO), G-CSF) to expand a portion of single CB units where the non-manipulated fraction was infused on day 0 and the remaining fraction was infused on day 10 of expansion [18]. While modest progenitor cell expansion (fourfold median) was achieved and no toxicities were observed, the time to neutrophil engraftment was not reduced as compared to historic controls [18]. Based on the favorable safety and feasibility data demonstrated in this trial, a double CBT randomized trial is currently underway in which patients are randomized to receive either two non-manipulated CB units or one non-manipulated unit and one unit expanded ex vivo [19]. Although interim analysis shows no significant difference in time to neutrophil engraftment overall, an effect was seen in a subset of patients who received reduced intensity conditioning (median time to neutrophil engraftment of 7 days vs. 14 days). Similarly, Kurtzberg and colleagues cultured a portion of a single CB unit for 12 days using the Aastrom Replicell bioreactor in the presence of cytokines but failed to achieve an improvement in neutrophil or platelet engraftment [20].

The above-mentioned studies demonstrate that cytokine-mediated expansion methods are safe but generate only moderate increases in progenitor cell numbers with at best modest improvements in clinically relevant outcomes such as time to neutrophil recovery. This lack of clinical success has led to a paradigm shift in current approaches to ex vivo expansion to target molecular pathways involved in stem cell self-renewal including those that play fundamental roles in governing cell-fate decisions throughout development. Our work with the Notch signaling system is an example of one such approach.

Pre-clinical approaches for ex vivo HSPC expansion: intrinsic and extrinsic regulators of cell fate

Optimization of cytokine-driven expansion systems has not led to clinically significant HSC expansion, perhaps due to a predominantly permissive, rather than directed, role in determining stem cell fate. The search for extrinsic and intrinsic regulators that act directly on human HSCs in regulating cell fate and self-renewal, homing/retention, and mobilization has suggested a role for regulatory molecules active in early development that are important in HSC maintenance and regulation. More recent studies have focused on the regulation of intrinsic signaling pathways by retrovirus-mediated transduction of HSCs, for example expression of homeobox genes, which have been shown to be involved in hematopoietic cell fate determination. However, culture of cells for clinical application requires the use of extrinsic regulators of cell development including bone morphogenic proteins (BMPs), angiopoietin-like proteins, IGFBP2, pleiotrophin, Sonic hedgehog (Shh), Wnt, and Notch ligands, or a combination of such factors.

For example, addition of Angptl5 and/or IGFBP2 to CD133$^+$ CB cells in culture has resulted in significantly improved in vivo reconstitution in NOD/SCID mice at 2 months post-transplant (0.8% vs. 11.3, 17.3, and 39.5% human engraftment for standard cytokines vs. standard cytokines plus IGFBP2, Angptl5, or both, respectively). Importantly, enhanced secondary transplantation was also observed [21]. Pleiotrophin, which has been found essential for maintenance of murine HSC, has recently been shown to modestly enhance ex vivo human CB HSPC expansion (twofold greater expansion of CD34$^+$38$^-$ cells compared to control) as well as in vivo reconstitution of immunodeficient mice with threefold improved human engraftment at 4 weeks and a sevenfold increase at 8 weeks post-transplant compared to uncultured control [22].

Retrovirally mediated overexpression of Hox transcription factors, in particular HoxB4, has led to extensive ex vivo HSC expansion in vitro (up to 3 logs over control cultures) with murine, human, and non-human primate HSC. Importantly, these transduced cells maintained full in vivo lymphomyeloid repopulating ability as well as the ability for serial transplantation [23–26]. However, clinical application of cells that have been genetically altered by virally mediated gene transfer is not preferred secondary to risk of insertional mutagenesis. Thus, stromal cell layers expressing a HoxB4 fusion protein have been used in the ex vivo expansion of human CB CD34$^+$ cells. The HoxB4 fusion protein is passively taken up by the CD34$^+$ cells, and the expanded cells resulted in a 2.5-fold increase in long-term repopulating cells compared to uncultured control [27]. The self-renewal induced by HoxB4 has resulted in further exploration of a variety of other extrinsic regulators of cell fate, particularly those known to play roles in stem-cell self-renewal, developmental and cell-cycle regulation, such as BMP-4, a member of the TGF-β superfamily, Shh of the Hedgehog family of proteins, and Notch ligands.

Through the use of transgenic mouse model systems, especially with respect to deconstructing the bone marrow microenvironment, and the extensive knowledge that has been gained over the last decade toward better understanding of the HSC niche, significant advances have been achieved toward ex vivo manipulation of HSC and its progeny. A variety of such identified molecules known to play roles in stem cell self-renewal, developmental and cell-cycle regulation, are currently being extensively evaluated, although to date they have not been manipulated for significant ex vivo expansion. In ex vivo expansion of human CB, soluble human BMP-4 has been shown to increase the survival of repopulating blood cells in ex vivo culture, while Sonic hedgehog has been shown to induce a few-fold increase in repopulating cells via mechanisms that are dependent on downstream BMP signals [28–31]. Likewise, the transcription factor SALL4, which has been implicated in the regulation of HSC self-renewal properties, when overexpressed in human hematopoietic stem/progenitor cells resulted in ex vivo expansion of cells capable of engraftment in an immunodeficient mouse model [32].

Wnt proteins, which are involved in the growth and differentiation of a variety of primitive tissues, have also been implicated in the regulation of hematopoiesis, possibly exerting their effects through stromal cells [33]; however, the role of the Wnt pathway in stem cell self-renewal based on gain- and loss-of function studies of Wnt pathway components remains controversial [34,35]. In studies with human CB progenitors, manipulation of the Wnt pathway through overexpression of Wnt5a or with glycogen synthase kinase-3B (GSK-3B) inhibitors did not augment expansion when added ex vivo to cultures but did enhance engraftment when infused in vivo post-transplant in irradiated mice [36–38]. There are also data supporting the presence of an interactive relationship between the various signaling pathways. For example, Notch-1 receptors have been shown to be upregulated in response to Wnt signaling in HSCs [39].

Additional potential targets have been identified that could result in expansion of HSCs ex vivo. For example, PI3-kinase-AKT pathway activation as a result of inactivation of the negative regulator PTEN has been shown to result in short-term HSC expansion but with long-term exhaustion of the stem cell pool [40]. Augmented stem cell self-renewal has been demonstrated in knockout murine models which result in inactivation of the cyclin-dependent kinase inhibitors p16Ink4a and p19Arf [41,42]. Finally, p21$^{-/-}$ mice demonstrate significantly impaired stem cell self-renewal, implicating p21, a downstream target of p53, in stem cell quiescence and a potential target [43]. Thus there is compelling murine data that these molecular pathways play an important role in the regulation of HSC self-renewal and thus may be applicable in human studies. However, the direct applicability to clinical translation is not yet known, especially as manipulation of these pathways, particularly those with tumor-suppressor function, may permit accumulation of mutations during stem cell culture, generating potentially oncogenic cells. Furthermore, as we begin to better understand more about the biologically distinct types of human hematopoietic cells that are responsible for early and long-term sustained hematopoietic recovery and the individual factors that are critical for these distinct subtypes, it is highly likely that the most effective approaches for clinical translation of expanded HSPC will require combinations of individually optimized approaches. Perhaps the most extensively studied and successfully utilized extrinsic regulators have been ligands that activate the Notch pathway, with now extensive studies indicating a role for the Notch family of receptors in mediating cell-fate decisions during hematopoietic development. We and others have shown that the Notch pathway enables hematopoietic stem and progenitor cells to sense the surrounding microenvironment and assume one of several cell fates, including myeloid and B-cell differentiation, self-renewal, or T-cell development. Furthermore, as described in the following section, our group has developed novel and clinically feasible methods utilizing engineered Notch ligands for the ex vivo expansion of human HSPCs for clinical application.

Notch signaling in hematopoiesis

Notch signaling was initially implicated as a critical pathway in hematopoiesis after our group's detection of the human *Notch-1* gene in CD34$^+$ or CD34$^+$Lin$^-$ human hematopoietic precursors in the early 1990s. As in multiple other developmental systems, the decisions that determine the fate of stem cells and their progeny result from intercellular interactions with adjacent cells within a given microenvironment and are modulated by several molecular families, including the *Notch* gene family [44–46]. The *Notch* gene encodes for a transmembrane receptor that is activated by binding of ligand to its extracellular domain. Four highly conserved Notch receptor paralogs (Notch-1–4) and five ligands (Jagged-1 and 2, and Delta-1, 3, and 4) have now been identified in vertebrates (for review, see [47,48]), with all four Notch receptors also detected in hematopoietic cells and the Notch ligands Delta-1 and Jagged-1 detected in human bone marrow stromal cells and human hematopoietic precursors [49–52].

Additional earlier studies by our group further demonstrated that use of a retrovirus to overexpress the intracellular domain of Notch-1 in primary murine HSC led to emergence of enhanced self-renewal and an immortalized pluripotent cytokine-dependent cell line capable of multilineage in vivo repopulation, demonstrating a role for Notch in HSPC self-renewal [53]. In addition, several investigators have now demonstrated that differential activation of Notch target genes results from selective activation of the different Notch receptors as a result of specific ligand interactions leading to different cellular outcomes. For example, activation of Notch-1 by Delta ligands 1 and 4 is required for inducing T-cell and inhibiting B-cell differentiation, while Notch-2 activation by Jagged-1 and possibly Delta-1 is sufficient to induce effects on HSPC [54–56].

These findings further suggested that manipulation of the Notch signaling pathway ex vivo in primary HSC could prove to be a novel approach for expanding HSPC. To this end and to avoid the potential safety concerns of retroviral transduction, we engineered a Notch ligand consisting of the extracellular domain of the Notch ligand Delta-1 in order to activate endogenous Notch signaling in HSPC during ex vivo expansion [57]. Initial use of engineered ligand immobilized to the tissue culture surface revealed profound effects on the growth and differentiation of isolated murine marrow precursors with a multilog increase in the number of Sca-1$^+$Gr-1$^-$ cells with short-term lymphoid and myeloid repopulating ability [58]. Similarly, studies with human CB CD34$^+$CD38$^-$ precursors cultured in serum-free conditions with immobilized ligand and cytokines resulted in an approximately 100–200-fold increase in the number of CD34$^+$ cells generated compared with control cultures, and included cells capable of repopulating immunodeficient mice [59,60]. Moreover, more recent studies with both murine and human hematopoietic progenitors have demonstrated density-dependent effects of Delta-1 on fate decisions of hematopoietic progenitors, and suggest that optimal ligand densities are required to promote expansion of cells that retain repopulating ability [59,61]. Other investigators have shown similar outcomes. Kertesz et al. demonstrated that culture of murine Lin$^-$ hematopoietic progenitor cells with immobilized Jagged-1 resulted in expansion of serially transplantable HSCs, with superior expansion dependent on the combinatorial effect of Notch and cytokine-induced signaling pathways [62]. Taken together, these data indicate that manipulation of Notch signaling can enhance stem cell self-renewal ex vivo and thereby increase HSC numbers for transplantation.

A key aspect of these studies was determination of whether the magnitude of Notch signaling played a role in the optimal generation of repopulating cells. Murine studies found that the relatively lower amount of Notch signaling induced in cells cultured with lower densities of Delta-1 led to self-renewal of progenitors with primarily B-lymphoid and myeloid potential whereas higher amounts of Notch signaling inhibited B-cell differentiation and promoted differentiation towards the T-cell lineage [61]. Concurrent studies with human CB also revealed important ligand dose-dependent effects whereby relatively lower densities of immobilized ligand substantially enhanced generation of NOD/SCID repopulating cells, whereas higher ligand densities promoted differentiation towards the T-cell lineage at the expense of repopulating cells [59]. An in vitro requirement for distinct Notch signal strengths presumably reflects selective in vivo usage of specific Notch receptor homologs with differing transcriptional activating strengths thus activating gene programs that are associated with stem/progenitor cell self-renewal versus those that promote early T-cell development. For example, Notch-2, which promotes HSPC self-renewal, may be a less potent transcriptional activator than Notch-1, which is required for T-cell differentiation [56].

Based on the above promising preclinical studies, methods utilizing an engineered Notch ligand for the ex vivo generation of increased numbers of CD34$^+$ cells is now under clinical investigation. The ability to generate increased numbers of HSPC is particularly important for patients undergoing CBT where both total nucleated and CD34 cell doses are limiting, resulting in delayed hematopoietic recovery and a higher risk of early transplant-related mortality. The development of methodologies for clinically feasible ex vivo expansion of CB-derived HSPC has generally been more successful than those using adult HSC derived from PBSC and BM. In the following section, our studies investigating the use of ex vivo expanded CB HSPC to augment CBT are discussed, along with other recent approaches under clinical evaluation and those under development.

Clinical trials using ex vivo expanded/manipulated cord blood HSPC

Rationale

With more than 30,000 CBT performed to date since 1988, CB has emerged as a source of HSC for hematopoietic cell transplantation. This is especially important for minority patients and patients of mixed ethnicity, for whom CB is a particularly attractive alternative donor stem cell source as it is readily available with no donor attrition and allows reduced stringency in human leukocyte antigen (HLA) matching without an increase in graft-versus-host disease (GVHD) [63,64]. Numerous clinical studies have consistently shown that the total nucleated cell and CD34$^+$ cell doses in CB grafts are highly correlated with the rate of neutrophil and platelet engraftment, as well as the incidence of graft failure and early transplant-related complication [65–70]. In fact, a recent analysis of adult single CBT (sCBT) recipients demonstrated that infused CD34$^+$ cell dose is the most important predictor of myeloid engraftment [71]. Furthermore, a recent publication from the groups at the Fred Hutchinson Cancer Research Center and University of Minnesota have shown that non-relapse mortality (NRM) is highest in double CBT (dCBT) recipients when compared to matched and mismatched unrelated donor recipients [72]. The majority of the NRM occurred within the first 100 days post-transplant with infection being the most common cause of death. Importantly, an analysis of the risk factors for NRM among dCBT recipients revealed a higher risk in patients with delayed myeloid recovery (time to ANC >500/μL) if the recovery was ≥26 days, the median time to engraftment in dCBT recipients. However, when the analysis of risk factors for NRM was restricted to include only those dCBT recipients engrafting before day 26, no difference could be found between the donor sources, emphasizing the important contribution of delayed engraftment to increased risk of NRM. Efforts to overcome the obstacle of small cell numbers in CB grafts by ex vivo cytokine-mediated expansion have not yet demonstrated improved time to engraftment. Infusion of multiple CB units as an alternative approach to increase cell numbers is now routinely used in adults and larger children; however, the significant delay in engraftment has not been abrogated in these patients [72,73]. Thus, the collective data point to improved outcome following CB transplantation in patients receiving a higher cell dose, in terms of both $CD34^+$ and total nucleated cell doses, an observation leading to the hypotheses that ex vivo expansion of $CD34^+$ cell numbers or the infusion of more than one unit of CB may improve the rate of CB engraftment and overall survival.

Several lines of evidence suggest that CB contains a higher frequency of primitive hematopoietic progenitor cells and early committed progenitors than adult bone marrow or peripheral blood with higher proliferative potential of CB HSPC in vitro in response to cytokine stimulation [74,75]. There is also increasing evidence that the CB-derived HSCs are less mature and have greater proliferative capacity [76,77]. A potential contribution to the differences observed between CB and adult HSCs may arise from the differential response of HSCs from different sources in cytokine-driven expansion systems, leading to variations in cell-cycle status and homing ability of the expanded cells. Other possible sources of stem cells may have even greater proliferative potential. For example, murine fetal liver cells have greater proliferation and repopulation potential than HSCs isolated from adult murine bone marrow or peripheral blood [78,79]. Overall, these results suggest that CB progenitor cells are functionally superior to adult bone marrow, with greater proliferative potential and possibly greater self-renewal capacity. Thus, CB may represent a more viable target for ex vivo stem cell expansion, a possibility that has led to several clinical studies on the ex vivo expansion of CB cells to augment conventional CBT.

Notch-mediated ex vivo expansion systems for clinical application

At the Fred Hutchinson Cancer Research Center, a phase I trial assessing the safety and ability of CB HSPCs cultured in the presence of an engineered form of the Notch ligand Delta-1 to contribute to rapid early engraftment in patients undergoing a myeloablative TBI-based CBT has just recently completed accrual. Final analyses are not yet available due to continued clinical follow-up in this small study of 23 patients in total, of whom 21 were evaluable for engraftment. One patient did not receive the expanded cell product as it did not meet release criteria and one patient experienced primary graft failure. The expanded cell product provided an average of 12.5×10^6 (median 8.3×10^6, range 0.9 to 49) $CD34^+$ cells/kg resulting from an average 178-fold expansion of $CD34^+$ for infusion. These cells were safely infused and led to a significant reduction in the time to neutrophil engraftment. The median time to neutrophil recovery (500/μL) was just 12 days compared to a median time of 25 days ($p < 0.0001$) in a concurrent cohort of 40 patients undergoing identical treatment but with two non-manipulated CB units (updated, unpublished data) [80]. Importantly, we have identified a cell dose relationship between $CD34^+$ cell dose/kg and time to rapid neutrophil recovery in recipients of partially HLA-matched expanded CB products, where 8 out of 11 patients who received greater than 8×10^6 $CD34^+$ cells/kg achieved an ANC ≥ 500/μL within 10 days. Median time to platelet engraftment was also encouraging at a median of 35 days (range 19–56) for platelets >20,000 (unpublished data).

Contribution to donor engraftment as derived from the expanded or non-manipulated grafts was determined weekly in the first month beginning at day 7 post-transplant on peripheral blood sorted cell fractions. Of the 21 evaluable patients, there were sufficient numbers of peripheral blood sorted myeloid cells for evaluation in all but one patient and in each of these patients revealed a predominance of donor cell engraftment derived from the expanded cell graft in both the CD33 and CD14 cell fractions. The one patient that was not evaluable at day 7 due to an insufficient quantity of cells had concurrent reactivation of HHV6, a virus that has been shown to inhibit progenitor cell proliferation [81]. To date, the expanded cell graft persisted beyond day 21 post-transplant in half of the patients (with three patients still too early to evaluate in vivo persistence) and 19 out of the 21 patients evaluable for engraftment experiencing engraftment prior to the median of 26 days seen in conventional dCBT recipients, suggesting a potential facilitating effect exerted by the ex vivo expanded cells on the non-manipulated CB graft. In addition, longer term in vivo persistence (defined as at least 6 months post-transplant) of the expanded cell graft has been observed in seven patients.

The observed in vivo persistence of the expanded graft to at least 6 months post-transplant suggests maintenance of some longer term repopulating progenitor cells despite ex vivo expansion. It remains unclear whether the lack of long-term engraftment from the expanded unit in the other patients represents loss of stem cell self-renewal capacity after in vitro culture or is indicative of immune-mediated rejection of the expanded unit (which is devoid of T cells) in vivo. In fact, our studies have also demonstrated T-cell-mediated effects to be responsible for rejection of one of two infused CB units in conventional dCBT [82]. Thus, it was surprising that in vivo persistence of cells derived from the expanded unit survived longer term in any patients as we anticipated eventual rejection of the expanded cell graft by the T-cell-containing, non-manipulated unit.

Although these preliminary studies of Notch-mediated expansion of CB repopulating cells points to the promise of expanding stem cells to achieve clinically relevant effects, phase II and III trials will be necessary to evaluate whether co-infusion of this expanded cell product decreases the occurrence of serious infection, improves survival, or affects duration of hospital stay in recipients of CB grafts. However, the 3–4 weeks required to identify and perform real-time, on-demand expansions of partially matched (at least 4–6 HLA-matched) CB units reduces the usefulness of this approach for treating patients at high risk of recurrent disease or to extend this therapy beyond CBT, for example to treat chemotherapy-induced neutropenia. To address this challenge, we developed a universal, "off-the-shelf," pre-expanded cellular therapy product which obviates the requirement for real-time production and HLA-matching due to the fact that this product is derived from enriched $CD34^+$ cells obtained from a single CB unit and is, therefore, devoid of T cells. We have now developed an optimized Notch-mediated expansion methodology specifically designed to expand HSPC isolated from fresh CB units. Following the 2–3 week expansion, the Notch-expanded cells are cryopreserved for future use as a universal donor product. Preliminary safety studies are currently underway to assess the safety and clinical feasibility of using this product to provide a transient myeloid bridge in a myeloablative CBT setting and in the non-transplant setting in adult patients with AML undergoing induction chemotherapy.

Other emerging approaches to ex vivo expansion

In addition to our trials using Notch-mediated expanded CB progenitor cells, there are currently several other approaches for the ex vivo expansion of CB HSPC under investigation, including ones based on culture with stromal elements to provide a "niche" for stem cell self-renewal or that have targeted defined molecules to achieve ex vivo expansion. A selection of clinical trials using ex vivo expanded CB progenitor cells is presented in the following, as are methods currently in the preclinical stage of development.

Stromal-cell based culture: Ex vivo expansion of HSPC using stromal-cell based co-culture systems have been explored as a means of providing an environment more analogous to the in vivo hematopoietic microenvironment which provides many of the molecular signals necessary for directing HSC self-renewal and proliferation as well as regulating their differentiation. To date, mesenchymal stem cells (MSC) have shown the most promise for use ex vivo as they are plastic adherent and seem to restore stromal interactions seen in the BM. In pre-clinical work using either CB or adult HSPC, it was demonstrated that modest expansion of the total nucleated and progenitor cell populations (up to 20- and 37-fold increases, respectively) could be achieved [83–85]. Based on these studies, Shpall and colleagues have recently published their initial results in 31 adult patients with hematologic malignancies utilizing the dCBT platform and a myeloablative conditioning regimen, in which they combine a non-manipulated CB unit with a unit that has been expanded for 14 days in the presence of cytokines (SCF, Flt3 ligand, G-CSF, and TPO) on either family member donor-derived MSCs or "off-the-shelf" MSCs (mesoblast) [86]. On day 14 the cells from the bags and the flasks are combined, washed and infused following the infusion of the non-manipulated CB unit. In this trial, they demonstrated a median 30-fold expansion of $CD34^+$ cells and a median time to neutrophil and platelet engraftment of 15 (range 9–42) and 42 (range 15–62) days, respectively. Importantly, no adverse events were attributed to the expanded cells and ultimately the unmanipulated unit was responsible for sustained donor engraftment. The cumulative incidence of neutrophil engraftment was 88% on day 26 which compared favorably to 53% in their control cohort of patients from the CIBMTR. Likewise, cumulative incidence of platelet engraftment at day 60 compared favorably to the CIBMTR control cohort at 71% and 31%, respectively. These studies confirm a potential role for cell-based HSPC expansion methodologies and suggest the need for further investigation to define the molecules responsible for these effects.

Copper chelator: Tetraethylenepentamine (TEPA): Based on the findings that cellular copper concentrations influence cell differentiation, Peled et al. evaluated the use of the copper chelator TEPA and cytokines (*TPO*, *Flt3 ligand*, *IL-6*, and *SCF)* in ex vivo culture of CB HSPC and demonstrated enhanced expansion of $CD34^+$ CB progenitors with improved SCID-repopulating ability [87,88]. Clinical trials have been conducted evaluating use of these expanded cells. In contrast to the other trials utilizing ex vivo expanded CB progenitors which have been based primarily on a double CBT model, in the initial phase I trial, Shpall and colleagues cultured a portion of a single CB unit with TEPA and cytokines for 21 days and co-infused these cells with the remainder of the untreated cell fraction. This approach was found to be safe and did result in sustained donor engraftment; however, there was no improvement in the kinetics of hematopoietic recovery [89]. Subsequently, a phase II/III, multicenter, multinational historical cohort-controlled study was conducted to evaluate the safety and efficacy of this approach ("StemEx®"). This trial, sponsored by Gamida Cell, was conducted at 25 bone marrow transplant centers worldwide in 101 patients with advanced hematologic malignancies and has completed accrual. Results have not been published at this time.

Aryl hydrocarbon receptor (AhR) antagonist: With the goal of identifying novel reagents that might be useful in HSPC ex vivo expansion, Boitano et al. used a 5-day culture assay with primary human $CD34^+$ cells and performed an unbiased screen of a library containing 100,000 heterocycles. Through this approach they identified a novel class of aryl hydrocarbon receptor antagonist (StemRegenin1 or SR1) found to be capable of enhancing $CD34^+$ cell generation from the blood of mobilized donors [90]. Similarly, SR1 was also found to significantly enhance the ex vivo generation of $CD34^+$ cells fivefold as compared to DMSO control after 3 weeks in cytokine-containing cultures and 50-fold after 5 weeks in culture. SR1-treated cells were found to promote retention of CD34 expression during the culture period. Of note, when in vivo limiting dilution transplants were performed in an immunodeficient mouse model, a 17-fold improvement in SCID-repopulating cells was observed as compared to uncultured cells. In addition, SR1-treated cells demonstrated enhanced long-term engraftment with 12-fold improvement in repopulation capacity following secondary transplant. These encouraging results have led to a phase I clinical trial using this technology, which has just recently initiated accrual. Similar to the previously reported studies, this study is being conducted in the myeloablative double CBT setting in which one unit is ex vivo expanded with SR1.

Alternative strategies to overcome the limiting cell dose in CB grafts: ex vivo modulation to enhance HSC homing

In addition to the ex vivo expansion strategies aimed at overcoming the limiting cell doses available in single and double CB grafts, significant efforts are underway to develop methods that enhance the efficiency of CB HSPC homing to the marrow microenvironment. Although not the focus of this chapter, this strategy deserves mention, as it is highly likely that overcoming the cell dose limitation associated, the use of CB grafts will depend on combination approaches where ex vivo expansion strategies are performed and the final product enhanced via ex vivo modulation to improve efficiency of marrow homing.

One example of ex vivo modulation to enhance homing is the pulse treatment of CB units prior to infusion with a prostaglandin derivative. Using a bench-to-fishtank-to-bedside approach, North et al. identified novel regulators of HSC self-renewal and proliferation in a high throughput identification screen and then demonstrated prostaglandin E2 (PGE2) as capable of enhancing HSC formation in zebrafish [91]. Likewise, pulse treatment of murine cells for 1–2 hours ex vivo with PGE2 prior to infusion also resulted in significantly higher numbers of repopulating cells being generated in a limiting dilution transplant model compared to uncultured control cells (3.3-fold at 6 weeks, 2.3-fold at 24 weeks). While its precise mechanism of action is unknown, PGE2 has been shown to interact with the Wnt pathway by increasing β-catenin expression levels [92]. In addition, ex vivo treatment of CB with dmPGE2 results in upregulation of genes involved in homing to the bone marrow (e.g., CXCR4), proliferation (e.g., CyclinD1), and survival (e.g., Survivin) [93,94]. Fate Therapeutics recently completed a phase Ib trial demonstrating that ex vivo modulation by pulse-treating CB units with a prostaglandin derivative for 2 hours prior to infusion is safe and accelerated neutrophil recovery by several days (Pratik Multani, personal communication). Based on these results, Fate Therapeutics are now evaluating this enhanced CB product (ProHema) in a multi-center phase II clinical trial.

Several additional pilot clinical trials have been conducted or are underway using various methods of ex vivo "priming" to enhance homing efficiency and sustained donor engraftment of CB grafts, including those targeting inhibition of CD26/dipeptidylpeptidase IV (DPPIV), fucosylation, and C3a priming [95–99]. All of these separate approaches are based on preclinical studies demonstrating enhanced homing and engraftment HSPC in murine models, with clinical trials that are currently underway or recently completed (results not published). The clinical impact of these approaches in improving outcomes following CBT is not yet determined. Moreover, the ability of ex vivo modulation to potentially impact multilineage engraftment, such as T-cell recovery, is also under investigation.

Conclusion

Although optimal conditions for expanding HSC numbers remain undefined, the collective results of studies outlined above suggest that enhanced short-term and long-term repopulating ability may be achievable with cytokine-induced expansion systems. However, these studies further suggest that cytokine-induced effects on HSC self-renewal and expansion remain limited, and clinically significant expansion has not been achieved with this approach. It is likely that we have not yet identified/optimized the critical factors and combinations required to induce symmetric HSC self-renewal. Thus current efforts are now focused on identifying and exploiting factors previously shown to regulate stem cell fate in other developing organ systems or during embryogenesis. This approach is beginning to yield promising results, and improved methods for HSC expansion are emerging. Identification of genes and regulatory elements that are responsible for preventing stem cell senescence and driving symmetric divisions of the HSC, and a better understanding of how culturing affects the homing ability of stem cells and of the complex cellular interactions in the bone marrow microenvironment, are all essential to the ultimate success of ex vivo expansion. These areas are discussed in more detail in other chapters.

Clinically, ex vivo expansion studies of primitive cells especially those using CB-derived HSPC have demonstrated the clinical feasibility of ex vivo expansion, and have suggested the enhancement of short-term repopulating cells perhaps at the expense of long-term repopulating cells. This is particularly relevant in patients undergoing myeloablative CBT where delayed myeloid engraftment is a known risk factor that is associated with the low CD34$^+$ cell doses provided in a single or double CB graft. Thus, with the goal of enhancing the time to myeloid recovery, sustained donor engraftment and decreasing the risk of early transplant-related mortality, extensive recent efforts have been aimed at expanding the available numbers of HSPC derived from individual CB units. The ultimate goal of this work would be the generation of short-term repopulating cells that meet an as of yet undefined threshold to abolish post-transplant neutropenia while providing long-term repopulating cells for sustained donor hematopoiesis. There are now several clinical trials underway using novel ex vivo expansion approaches that demonstrate great promise towards the generation of clinically meaningful absolute numbers of repopulating cells.

As discussed earlier, other investigators have focused on improving homing efficiency of the limiting numbers of HSPC in CB grafts by ex vivo modulation. While this approach may improve the incidence of sustained donor engraftment, it is not likely to result in a significant reduction in the duration of post-transplant neutropenia due to overall lower numbers of both HSPCs and more committed progeny in the primary graft. The achievement of reliable reduction of post-transplant cytopenias using ex vivo expanded cells is likely dependent on a combination of approaches that are aimed at enhancing the absolute number of HSPCs for transplant and increasing the efficiency of these expanded cells to home to the marrow microenvironment.

Despite the many promising approaches highlighted above, challenges clearly remain. A key issue is the expansion of the long-term repopulating HSC for indications such as gene therapy versus abrogation of the prolonged neutropenia that occurs following high-dose chemotherapy and radiation as in myeloablative CBT which has been successfully demonstrated with the infusion of short-term repopulating progenitors. The cost of these approaches will also ultimately affect the application of stem cell expansion methodologies. Currently, these therapies are not economically feasible and will require clear demonstration of improved patient outcomes such as more rapid hematopoietic recovery and therefore decreased transfusion requirements and decreased infections as well as a reduction in the number of days in the hospital, to be considered. Development of biologically based culture systems, such as that developed by Csaszar et al. represent important steps in cost reduction and improved expansion [2]. In their "fed-batch" system, the inhibitory factors that accumulate in culture and prevent ongoing expansion of HSPCs over time are addressed real time through computational approaches to design an optimal "feeding" schedule. Furthermore, bioprocesses involving cell selection, investigation of novel bioreactors that may recreate an artificial stem cell niche, effectively utilizing or re-utilizing media and cytokines, and three-dimensional lattices allowing for maximal expansion will certainly contribute to better optimized, cost-effective approaches [100–102].

Another aspect of ex vivo expansion that cannot be overlooked is the need to ensure safety of the expanded cell products, particularly when pathways that maintain genomic integrity may be perturbed allowing for aberrant differentiation and/or oncogenesis. New techniques for global assessment of the genome and epigenome will enable assessment of whether the genome and chromatin landscape of the expanded cell populations accurately reflect their non-manipulated counterparts and thus are predictive of appropriate cell behavior. During the next few years, we can expect that further development of the promising methods described herein will result in substantially enhanced generation of HSPCs for clinical application, and importantly, the effectiveness of such approaches will be tested in randomized clinical trials.

CHAPTER 7

Mesenchymal Stromal Cells and Hematopoietic Cell Transplantation

Edwin M. Horwitz
Nationwide Children's Hospital, The Ohio State University College of Medicine, Columbus, OH, USA

Introduction

Hematopoietic cell transplantation (HCT) is a well-established therapy for hematologic malignancies as well as many non-malignant disorders. Over the last several years, the spectrum of diseases that may be treated with HCT has dramatically expanded increasing the importance of this therapeutic modality and extending HCT beyond the traditional bounds of hematology and oncology.

HCT is founded on the principle that hematopoietic stem cells (HSCs) can be intravenously infused, will home to and engraft in the stem cell niche within the bone marrow microenvironment, and then proliferate and differentiate to repopulate all lineages of the blood. The cells that comprise the microenvironment support, and regulate hematopoiesis. However, one cellular constituent of the microenvironment, the marrow mesenchymal stromal cells (MSCs), may have quite complex biologic functions that can be exploited in the development of primary or adjunct cell therapy with HCT or in regenerative medicine.

MSCs are spindle-shaped plastic-adherent cells isolated from bone marrow as well as other tissue sources [1]. First recognized nearly 50 years ago [2], MSCs have emerged as one of the most rapidly evolving areas of research in HCT. The trilineage differentiation of MSCs, capable of giving rise to osteoblasts, chondrocytes, and adipocytes in vitro, led investigators to hypothesize a vast differentiation potential and focus research on the regenerative capacity of MSCs in an effort to repair diseased or damaged tissue. More recently, MSCs have been recognized to possess striking immunomodulatory properties and it is this characteristic of MSCs that has generated the greatest interest among physicians and investigators in the field of HCT [3,4]. Indeed, MSCs produce an extensive array of immunomodulatory cytokines as well as a variety of other, known and likely undiscovered, biochemical mediators. The secretion of these biologic response modifiers has proven to be the most biologically and clinically important property of MSCs [5].

While MSC research continues along many avenues, this chapter will focus on the biology and clinical applications of MSCs in HCT.

Brief history of MSCs

The notion that a mesenchymal progenitor cell with osteogenic differentiation potential resided within bone marrow was considered in the latter nineteenth century. However, it was the pioneering work of Alexander Friedenstein that first identified the cells which now bear the designation "MSC" [2]. He showed that these cells were precursors for osteoblasts, comprised the hematopoietic microenvironment, and that a fraction of the population, cells he termed CFU-F, possessed a high proliferative potential demonstrated by forming clonal colonies when plated at low density. Friedenstein went on to demonstrate the extensive expansion potential showing that single cells could regenerate an entire population of cells, suggesting that individual cells were precursors for fibroblasts in vivo [6]. However, Friedenstein did not suggest that the marrow stromal fibroblasts that he had identified were stem cells.

The first formal presentation of the concept that a non-hematopoietic stem cell may reside within the bone marrow microenvironment was by Maureen Owen [7]. She proposed that the marrow stroma consisted of a lineage of cells analogous to the hematopoietic system. She then expanded this theory and proposed a stromal stem cell with fibroblastic, osteogenic, and adipocytic cells being the terminally differentiated phenotypes. The term mesenchymal stem cell was proposed by Arnold Caplan hypothesizing that this cell could differentiate to a wide variety of mesenchymal tissues and proposed a broad lineage "tree" suggesting that the mesenchymal stem cell could give rise to bone, cartilage, muscle, hematopoietic-supportive stroma, tendon, ligament, adipose, and other connective tissues [8]. Data demonstrating the identification of MSCs by reactivity with the monoclonal antibodies SH2 and SH3, the considerable self-renewal capacity, and the multilineage differentiation potential in vitro supported the notion that these cells were a homogeneous population of stem cells [9]. However, more recent data demonstrated that the adherent cells isolated from marrow are a heterogeneous population of cells [10,11], although a non-hematopoietic stem cell may exist within this cell population [12]. Many other investigators, too numerous to recount here, have made important contributions to the scientific development of MSCs.

At present, MSCs are generally accepted to be a heterogeneous population of cells with diverse biologic properties suggesting a remarkable potential as cell therapy. The cytokine-generating and immunomodulatory properties portend a substantial impact in HCT.

Nomenclature

The nomenclature of these cells merits clarification. MSCs have been designated by a wide variety of terms including marrow stromal cells, marrow stromal fibroblasts, and most often mesenchymal stem cells, which was the basis for the acronym, MSC. While the specific properties of MSCs studied in the laboratory may vary

depending on the methods of isolation and culture expansion, the assortment of terms, in general, refer to the same heterogeneous population of cells.

The term "stem cell," however, implies specific biologic properties. Our general concept of a stem cell evolved from our understanding of the hematopoietic stem cell. Till and McCullough suggested that the stem cell could be defined as a cell with extensive self-renewal capacity and the potential to terminally differentiate into two or more lineages [13]. While MSCs can, indeed, undergo extensive self-renewal and trilineage differentiation to osteoblasts, chondrocytes, and adipocytes in vitro, true "stemness" is certainly much more complex and may be best defined operationally. As this idea became increasingly recognized, many investigators suggested that convincing data were lacking to support the notion that the unfractionated population of plastic adherent cells from bone marrow designated as MSCs are properly considered as *stem* cells [14].

While a legitimate mesenchymal stem cell most assuredly exists [15] the entire unfractionated population of cells isolated by plastic adherence that we designate as MSCs does not meet the criteria of a homogeneous population of stem cells. Therefore, in 2005, the Mesenchymal and Tissue Stem Cell Committee of the International Society for Cellular Therapy (ISCT) recommended that the term *mesenchymal stromal cell* is a more appropriate designation for this heterogeneous population of cells, maintaining the acronym "MSC" while reserving the term, "mesenchymal stem cell," for a unique cell that demonstrates stem cell activity in vivo by clearly stated criteria [14]. Nearly 10 years since this nomenclature was proposed, the terminology is now largely used by the MSC community.

Biologic role of MSCs in situ

The search for the physiologic mesenchymal stem cell has generated great interest among investigators. Over the last several years, important data have emerged which revealed much biology but also generated much controversy.

Sacchetti et al. identified a CD146-expressing stromal cell from human bone marrow [16]. In situ, these CD146 cells reside in the subendothelial layer in sinusoidal walls as adventitial reticular cells. CD146 expression is found on all CFU-Fs and their clonal progeny, but on only about 30% of the heterogeneous populations of stromal cells. After isolation and ex vivo expansion, the CD146-expressing cells were capable of forming the hematopoietic microenvironment, including bone and marrow space, in heterotopic locations after subcutaneous transplantation into immune-deficient mice. Bone was evident at 4 weeks after transplantation. Then, capillaries formed and developed into a system of sinusoids similar to human bone marrow. The endothelium of the sinusoids was murine, but the adventitial cells were human indicating that the transplanted human adventitial cells were capable of self-renewal. Adipocytes were also observed in the developing marrow space. By 8 weeks, murine hematopoietic cells had migrated into and colonized the marrow space of the regenerated bone. Thus, the CD146-expressing cells isolated from human bone marrow and accounting for all CFU-Fs, seemed to be able to give rise to bone and the entire bone marrow microenvironment sufficient to attract primitive hematopoietic cells and support the ensuing hematopoiesis.

Crisan et al. reported that CD146-expressing cells exist as pericytes in multiple human organs [17]. These cells expressed typical MSC markers, lacked hematopoietic markers, and differentiated to osteoblasts, adipocytes, and chondrocytes thereby meeting the criteria for MSCs. Interestingly, the cells exhibited myogenic potential in vitro and in vivo. These studies bear resemblance to prior reports suggesting MSCs isolated from different tissue sources show different gene expression profiles and the expression patterns, in some cases, seem to reflect the tissue from which they were derived [10]. Moreover, these two studies are consistent with the evolving paradigm of MSCs that ostensibly similar cells isolated from different tissues may have markedly different biologic – and therapeutic – potential. Furthermore, it underscores the need to consider the source of MSCs in the development of MSC-based cell therapies.

While murine MSCs share some characteristics with their human counterparts they also seem to differ in many ways [18]; hence, murine studies of MSC biology must be interpreted with the understanding of potential interspecies differences. Such caution notwithstanding, murine studies have also shed light on the physiologic role of MSCs. Morikawa et al. identified a subset of cells from the heterogeneous population of MSCs of murine bone marrow characterized by platelet-derived growth factor receptor α (PDGFRα) and stem cell antigen 1 (Sca-1), termed PαS cells. The population was highly enriched for CFU-Fs, expressed common MSC markers, was capable of self-renewal in vitro, and underwent differentiation to osteoblasts, adipocytes, and chondrocytes. Unexpectedly, these cells also seemed to differentiate to endothelial cells. In healthy mice, the cells were found in the perivascular space, similar to the human CD146-expressing cells which we presume are human MSCs [16,17]. After intravenous transplantation of fresh cells (without ex vivo expansion), the PαS cells gave rise to osteoblasts and adipocytes as well as perivascular cells, consistent with stem cell-like behavior.

Mendez-Ferrer et al. [19] have identified a nestin-expressing MSC within murine bone marrow. While the cells were found exclusively in the perivascular region adjacent to bone or within the bone marrow, they were distinct from typical vascular endothelial cells. The nestin-expressing MSCs contained all CFU-Fs and exhibited the differentiation characteristics attributed to MSCs. Interestingly, the cells were able to undergo self-renewal in serial transplantation, although they were propagated in vitro as non-adherent aggregates termed mesenspheres. In vivo, these cells were intimately associated with HSCs and seemed to be critically important for HSC homeostasis and marrow homing of transplanted HSCs.

Park et al. [15] identified an *Mx1+* stromal cell within murine bone marrow that migrates to injured tissue and gives rise to osteoblasts at fracture sites. Importantly, single cell transplantation studies revealed progenitor self-renewal as well as progeny differentiation to osteoblasts. Moreover, these cells were capable serial transplantation, one of the hallmarks of "stemness." The cell identified by Park et al. seems to most closely correspond to the prevailing view of clinically applied MSCs; however, the differentiation potential of this cell was restricted to the osteolineage.

Bianco et al. [20] have recently offered a perspective on the translation of MSC biology into clinical trials. While several important issues were brought to light, prominent laboratory-based and clinical investigators with a vast collective experience in this field rebutted the perspective emphasizing the most basic principles of experimental medicine as well as the incalculable potential differences between a mesenchymal (stem) cell in situ and the ex vivo expanded cells [21,22].

Taken together, these studies illustrate the important, evolving biologic paradigm of mesenchymal stem cells and underscore that MSCs as agents of cell therapy after ex vivo expansion may bear little biologic resemblance to their physiologic counterparts in situ. Thus, understanding the engineered biology of ex vivo expanded MSCs, utilizing the irreplaceable data derived from clinical trials, is critically important to the development of effective cell therapy.

Working definition of ex vivo-expanded MSCs for clinical cell therapy

MSCs are a heterogeneous population of cells that defy simple definition because, presently, no specific marker or combination of markers is accepted to uniquely define the cells. Moreover, we lack a single functional assay that distinguishes MSCs, analogous to the repopulation assay for HSCs.

To begin to address this issue, the Mesenchymal and Tissue Stem Cell Committee of ISCT, in 2006, sought to standardize a current working definition of MSCs by proposing a set of minimal criteria to denote MSCs [23]. First, MSCs must be plastic-adherent when maintained in standard culture conditions. Second, MSCs must express CD105, CD73, and CD90, and lack expression of CD45, CD34, CD14 or CD11b, CD79 or CD19, and HLA-DR surface molecules. Third, MSCs must differentiate to osteoblasts, adipocytes, and chondroblasts in vitro (Figure 7.1, Table 7.1). These criteria are by design very general and do not indicate any specific biologic activity. While they will certainly require modification as new knowledge unfolds, despite the description of several novel surface markers of MSCs [24], a more functionally relevant surface phenotype has not yet been described.

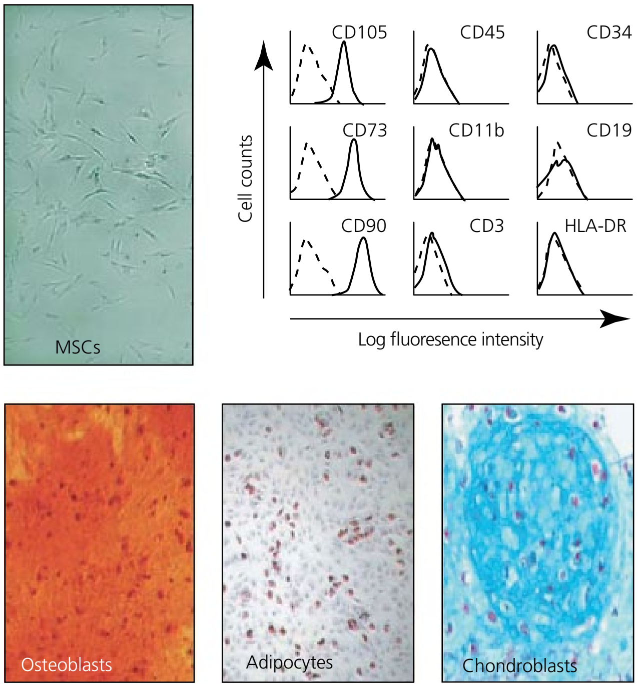

Figure 7.1 A panel of data demonstrating the defining characteristics of MSCs: adherence, immunophenotype, and in vitro differentiation. (Top, left) Photomicrograph of undifferentiated MSCs showing the characteristic spindle shape and adherent properties of the cells. Original magnification, ××40. Cell biology of ex vivo expanded MSCs

Tissue sources

MSCs are most commonly isolated from bone marrow [25] or adipose tissue [26], but have also been obtained from placenta [27], and umbilical cord blood [28]. Mobilized peripheral blood cells have been reported as a source of MSCs [29]; however, current consensus is that MSCs do not circulate in cytokine-mobilized or steady-state peripheral blood. Reports of MSCs in umbilical cord blood have also been conflicting; however, we now recognize that cord blood unit storage time, volume, and cell count are critical parameters affecting the efficiency of MSC isolation [28] and there is general agreement that MSCs do reside within cord blood.

Isolation

MSCs are most often isolated by "adherence selection." For bone marrow, mononuclear cells are placed in tissue culture and the MSCs will adhere to the plastic surface of the tissue culture vessel. Non-adherent cells are easily removed by changing the tissue culture media. Similar protocols are used when MSCs are isolated from other tissue sources. Prospective isolation of MSCs using surface markers has been pursued; however, in all cases, culture expansion of the selected cells was required to obtain a sufficient sample for further study. If prospective isolation of MSCs is to become a common practice, a substantial advantage must be demonstrated.

Phenotype

The expanded MSC product is a heterogeneous population of cells most easily demonstrated by in vitro adipocyte differentiation where only a subset of cells develops cytoplasmic fat globules and a CFU-F assay where a small fraction of cells exhibit a high proliferative colony-forming potential. However, this assorted population does have some common characteristics. The uniform surface phenotype of MSCs includes expression of CD105, CD73, and CD90 which can be used to define the cells, as well as CD49b, CD49e, CD166. STRO-1, an IgM monoclonal antibody generated by inoculating mice with human CD34^{+} cells, binds to human MSCs (or perhaps MSC precursors) in freshly isolated bone marrow, but does not bind to murine MSCs or human MSCs in tissue culture [30]. The antigen recognized by STRO-1 has not been identified. The low affinity nerve growth factor receptor, LNGFR or CD271, is also expressed on human MSCs in freshly harvested bone marrow but not culture-expanded cells [31]. Ex vivo expanded MSCs lack expression of hematopoietic and endothelial antigens, CD34, CD45, CD3, CD19, CD14, CD11b, and CD31.

MSCs demonstrate a surface antigen profile predicted to be hypoimmunogenic. At baseline, MSCs express moderate levels of HLA class I molecules but lack expression of HLA class II molecules on the cell surface. Upon stimulation with interferon γ in vitro, Class II antigens are found on the cell surface. MSCs do not express co-stimulatory molecules CD80, CD86, CD40, and CD40L [32].

One of the most distinguishing characteristics of MSCs, in contrast to other spindle-shaped, plastic-adherent cells, is the capacity for trilineage differentiation in vitro. MSCs differentiate to osteoblasts, chondrocytes, or adipoctyes when cultured under linage-specific inductive conditions and the cells can be identified by either tissue-specific immunohistochemical staining, for example, Oil Red O to identify the cytoplasmic fat globules of adipocytes, or gene expression.

Ex vivo expansion

MSCs have a remarkable capacity for ex vivo expansion. In standard culture conditions, MSCs isolated by adherence selection demonstrate a population doubling time of about 2 to 5 days [33]; however, plating cell density can impact the expansion potential [34]. Most MSC preparations can be maintained in continuous culture for 4–6 months before senescence. MSCs isolated from different species exhibit differing growth potentials. While human MSCs rapidly expand in culture, murine MSCs expand more slowly. Moreover, different mouse strains show a marked difference in growth and differentiation [18].

MSC cultures require some serum supplementation although serum-free media is under development. Fetal bovine serum has been the most commonly used supplement and continues to be the standard in the laboratory. The rapidly increasing clinical applications of MSCs in addition to the report of a clinically significant immune response against fetal bovine serum proteins in one patient who received MSCs [35], has led to the development of human serum/platelet lysate [36] supplementation which is rapidly becoming the clinical standard.

Secretome

MSCs have an enormous capacity for secretion of soluble mediators, and indeed, it is these mediators that comprise the principle mechanism of biologic/therapeutic activity. MSCs secrete stromal derived factor-1 (SDF-1) [37], which plays a critical role in the homing of HSCs to the marrow niche [38]. In vitro, MSCs constitutively secrete interleukin (IL)-6, IL-7, IL-8, IL-11, IL-12, IL-14, IL-15, macrophage colony-stimulating factor (M-CSF), Flt3 ligand, and stem cell factor (SCF). Upon IL-1α stimulation, MSCs are induced to further express IL-1α, leukemia inhibitory factor (LIF), granulocyte colony-stimulating factor (G-CSF), and granulocyte–macrophage colony-stimulating factor (GM-CSF) [32]. Finally, MSCs can secrete several chemokine ligands including CCL2, CCL4, CCL5, CCL20, CX_3CL1, and CXCL8 [39].

Importantly, the list of cytokines secreted by MSCs is rapidly growing. The secretome of an MSC product is, in part, dependent on the tissue source and the conditions of ex vivo expansion [10,11]. In theory, then, specific tissue sources can be identified and specific expansion protocols can be developed to generate a secretome that is especially well suited for specific clinical indications. Indeed, the search for as yet undescribed cytokines generated by MSCs and processing conditions to induce expression of specific cytokines or other mediators are two areas of exceptionally active investigation.

Homing and migration

Homing refers to a specific biologic process in which cells localize to a defined tissue typically mediated by chemotactic factors or ligand–receptor interactions. MSCs do not seem to home to the bone marrow space; however, the cells can be engineered to home to the bone endosteum [40].

Lifespan of MSCs

The lifespan of ex vivo expanded MSCs after intravenous infusion is difficult to conclusively prove; however, three lines of evidence suggest MSCs persist about 6–9 months in the recipient. First, Nolta et al. infused human IL-3 secreting-MSCs into NOD-SCID mice to support human hematopoiesis and were able to detect human IL-3 in the murine serum for up to 9 months [41]. Second, Horwitz et al. infused human MSCs into children with osteogenesis imperfecta and observed a striking acceleration of growth velocity over the first 6 months with a subsequent slowing of growth [35]. Most recently, von Bahr et al. reported DNA evidence of donor MSCs in autopsies of patients who died within 50 days of the MSC infusion, but not long term [42].

Immunobiology

While the detailed mechanisms of the MSC immune modulation remain to be fully elucidated, MSCs unquestionably have a profound impact on immunity and considerable progress over the past several years has brought some clarity to this arena [43,44]. While the field is rapidly advancing, several overriding themes emerge. First, all arms of the immune system interact with MSCs. Second, there seems to be a dynamic cross-talk between the immune effector cells. Third, substantial differences between murine and human MSCs as well as the immune systems, suggest caution when extrapolating murine findings to humans and translating laboratory discoveries to the clinics. Indeed, resolution of a major scientific controversy came from the recognition that immune suppression by murine MSCs is principally mediated by nitric oxide (expression of inducible nitric oxide synthase, iNOS) while indoleamine 2,3-dioxygenase (IDO) and heme-oxygenase-1 (HO-1) primarily underlie human MSC activity [45].

The immunomodulatory properties of MSCs may be exploited therapeutically to suppress graft rejection, treat severe graft-versus-host disease (GVHD), and possibly prevent clinical GVHD. Indeed, the recognition that MSCs can suppress the immune response is what attracted the collective attention of the HCT.

T lymphocytes

The first studies to suggest that MSCs may possess inherent immunomodulatory properties were based on the recognition that ex vivo expanded third party human MSCs inhibit the proliferation of allogeneic lymphocytes in a mixed lymphocyte reaction (Figure 7.2) [46]. The effect is non-specific as MSCs inhibit the proliferation of T cells in response to alloantigens [47–49] and mitogens [46], and it is MHC-unrestricted as both allogeneic and autologous MSCs

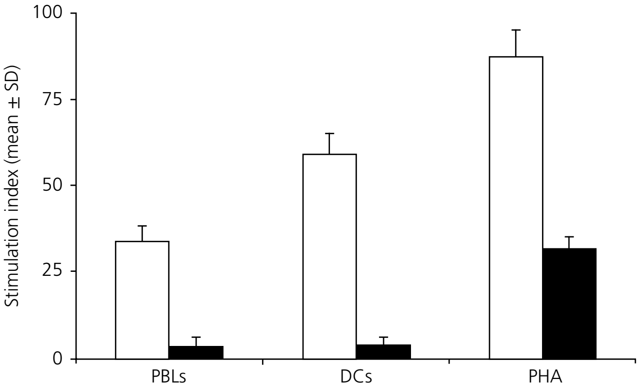

Figure 7.2 Mesenchymal stromal cell (MSC)-induced suppression of T-cell proliferation in response to allogeneic peripheral blood lymphocytes (PBLs), dendritic cells (DCs) or phytohemagglutinin (PHA) in a mixed lymphocyte reaction. Seven-day mixed cultures were performed with (black bars) or without (white bars) MSCs. Data are expressed as mean ± standard deviation (SD) of triplicates of six separate experiments. *Statistically significant (minimum $p = 0.004$). Source: Di Nicola et al. 2002 [46]. generate a similar suppression [47–50]. The antiproliferative effect of MSCs has been reported to resemble divisional arrest anergy of activated T cells based on evidence that MSCs induce a cell cycle arrest in the G_1 phase which persisted after removal of the MSCs from the in vitro culture [51]. In contrast to T cell anergy in general, MSC-induced T cell anergy can only be partially overcome by IL-2. MSCs also inhibit the cytotoxicity of T lymphocytes [48], increase the proportion of $CD4^+CD25^+FoxP3^+$ regulatory T cells, which possess inherent potent immune suppressor activity [52], and inhibit the differentiation of $CD4^+$ T cells into Th17 cells and suppress cytokine production [53]. Finally, MSCs decrease interferon γ production by Th-1 cells, and increase interleukin-4 by Th-2 cells, suggesting a shift from a pro-inflammatory to an anti-inflammatory state [54].

B lymphocytes

MSCs also interact with B lymphocytes, although the effects are unclear. MSCs seem to inhibit B-lymphocyte proliferation in vitro via divisional arrest anergy, impair B-lymphocyte maturation and antibody secretion, and decrease the chemotactic properties [55–57]. By contrast, some studies have suggested that MSCs support the survival, proliferation, and differentiation of B lymphocytes to mature, antibody-secreting cells [58,59].

NK cells

MSCs inhibit IL-2- and IL-15-induced proliferation of freshly isolated, resting NK cells and prevent the induction of cytotoxic activity and cytokine production; however, proliferation of NK cells preactivated with IL-2 was only partially inhibited [60–62]. Interestingly, MSCs seem to be highly susceptible to NK cell-mediated lysis due to expression of surface ligands involved in NK cell activation, such as NKG2D and DNAX accessory molecule-1 ligands [60] as well as low level MHC class I expression. However, ligand expression varied considerably among different MSC preparations which translated to widely discrepant results of NK cytotoxicity assays and may suggest strategies to generate MSCs for specific clinical applications. Importantly, MSCs exposed to interferon γ in vitro which upregulates MHC class I expression on MSCs led to reduced susceptibility to measured NK cytotoxicity, which may impact the in vivo MSC-immune interactions and therapeutic applications.

Dendritic cells (DCs)

MSCs can inhibit the differentiation of $CD14^+$ monocytes and $CD34^+$ cells into DCs as well as the maturation and function of DCs in vitro [63,64]. MSC co-culture inhibited the GM-CSF-, IL-4-induced differentiation of monocytes to DCs, but the inhibition was reversible. MSC-DC co-culture also induced mature DCs to downregulate surface expression of CD83, CD1a, CD80, CD86, and HLA-DR as well as IL-12 secretion. Moreover, MSC-treated DCs showed an impaired capacity to prime allogeneic T cells, consistent with the observation that MSCs direct DCs to acquire a tolerogenic phenotype.

General mechanisms of immune modulation

The molecular mechanisms of MSC-mediated immune suppression are the central focus of much research in this field leading to an increasingly clear understanding. In general, immune modulation is currently thought to be mediated by secreted factors in contrast to cell-to-cell contact. Factors considered to be essential for MSC immune suppressive activity include galectins, prostaglandin E2, transforming growth factor β, human leukocyte antigen G5, and TNFα-stimulated gene 6 protein. Additionally, three metabolic enzymes are central: IDO, HO-1, and iNOS. Interestingly, the adhesion molecules intercellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1) have been reported to correlate with the immune suppressive activity of MSCs suggesting the possibility of a contact-dependent mechanism as well [65].

Immune privilege

MSCs are considered to be immune privileged by many investigators [66]. Indeed, MSCs exhibit a hypoimmunogenic phenotype and do not elicit a T-cell proliferative response in vitro. Moreover, HLA-disparate MSCs can be safely infused into patients and often demonstrate a therapeutic effect, for example in the treatment of GVHD [67,68]. However, it is not strictly correct to infer immune privilege from such data. Immune suppressive activity and immune privilege are distinct biologic properties and immune suppression does not a priori indicate immune privilege. Murine studies and in vitro studies of human MSCs do not necessarily reflect clinical (in vivo) immune activity and infusion of allogeneic MSCs into immunosuppressed hosts does not provide data to support (or refute) the immunogenicity of the cells.

An early observation to persuasively suggest human MSCs can be recognized by the immune system and may function as an antigen-presenting cell in patients, came from a clinical trial of intravenous infusions of gene-marked MSCs in (immune-competent) children with osteogenesis imperfecta [35]. In this first trial of allogeneic MSC infusions in humans, the MSCs were ex vivo expanded in fetal bovine serum (10%)-containing media, divided into two fractions for retroviral transduction with either a vector expressing the neomycin phosphotransferase gene (neo^R), a bacterial protein, or a non-expressing vector and then both cell populations were infused into the patients without an immunosuppressive preparatory regimen. In all evaluable patients, cells containing the non-expressing vector were identified while cells expressing the bacterial protein, neo^R, were never identified (Figure 7.3). This observation suggests the possibility that the MSCs expressing neo^R were immunologically recognized in the immunocompetent hosts. Additionally, an in vitro cytotoxicity assay using mononuclear cells obtained from patients after the cell infusions revealed lysis of autologous MSCs transduced with the neo^R-expressing retroviral vector but not of MSCs transduced with the silent vector (Figure 7.4) supporting the notion that the neo^R-expressing cells were subject to immune recognition and elimination. Finally, neither fraction of cells was identified in one patient. This child developed hives and urticaria promptly after the second MSC infusion. Assay of antifetal bovine serum antibodies in the patients revealed that this patient had a 160-fold increase in antibody titer in the post-MSC infusion serum compared with the pre-infusion serum and he was the only child to exhibit a rise in titer (Figure 7.5). Together with the laboratory data of Spees et al. who showed that MSCs internalize fetal bovine serum proteins from the culture media [69], these clinical data suggest that fetal bovine serum proteins were taken up from media and the processed peptide antigens were presented by the MSCs to elicit a systemic immune response in this patient.

The preponderance of current data suggests that MSCs are not intrinsically immune privileged, and, in fact, may stimulate an immune response in some conditions. However, MSCs seem to be hypoimmunogenic due to their low-level expression of MHC molecules and complete lack of co-stimulatory molecule expression and this property may be exploited in a variety of clinical settings. To be sure, the use of allogeneic HLA-unmatched MSCs appears to be safe and elicits a therapeutic response in some patients.

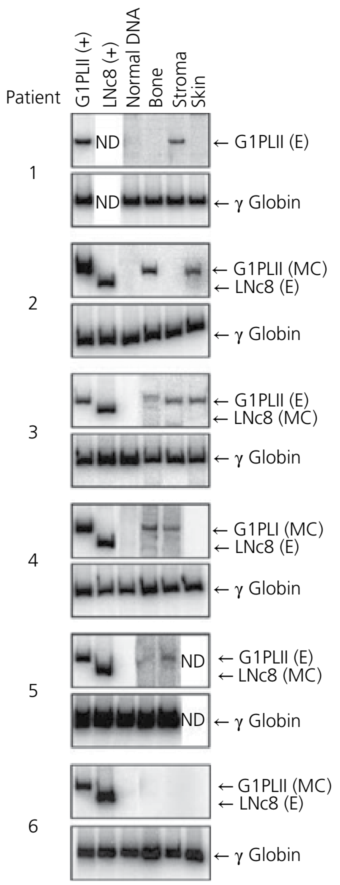

Figure 7.3 A polymerase chain reaction analysis for the gene-marking vector sequences in DNA isolated from osteoblasts, stromal cells, and skin fibroblasts of each patient, at 4–6 weeks after two infusions of gene-marked mesenchymal stromal cells (MSCs). DNA isolated from human cells transduced with either the G1PLII or LNc8 vector served as a positive control; normal human DNA was the negative control. Analysis of the gamma-globin (γ Globin) gene controlled for the quality and quantity of DNA. MC and E designate whether the signal represents minimally cultured cells or expanded cells, respectively. The vectors were alternated among the patients to avoid vector bias. ND, Not determined. Source: Horwitz et al. 2002 [35]. Reproduced with permission of National Academy of Sciences.

Risks of ex vivo expanded MSCs as cell therapy

Malignant transformation

MSCs invariably undergo ex vivo expansion for all clinical applications. This extensive cell replication raises the possibility of spontaneous transformation to a malignant phenotype, the most serious potential adverse event in a clinical trial. Murine MSCs seem to more readily undergo malignant transformation than human MSCs [70] possibly due to their significantly greater susceptibility to chromosomal aberrations and spontaneous mutations with prolonged culture [71] suggesting that such models are not good predictors of transformation of human MSCs in clinical trials.

Although there are several reports of malignant transformation of MSCs in vitro, the two most often cited studies [72,73] have been retracted [74,75] as the corresponding authors found their results were due to contamination of the MSC cultures by malignant cell lines. Further studies have confirmed the lack of spontaneous transformation [76]. During ex vivo expansion, MSCs may acquire chromosomal aberrations which have been suggested to predict the likelihood of malignant transformation [77]. However, such theoretical predictions have not been validated and substantial data to the contrary has been presented [78,79].

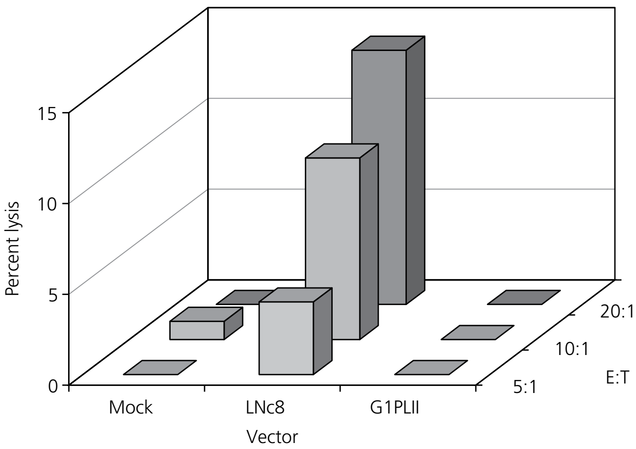

Figure 7.4 The cytotoxic response of peripheral blood mononuclear cells against transduced mesenchymal stromal cells (MSCs) is depicted. The immune cell-mediated lysis of donor MSCs transduced with the LNc8 retroviral vector (expressing neoR) in contrast to MSCs transduced with the G1PLII vector (no transgene expression) or mock supernatant. Malignant transformation of MSCs after infusion into human subjects in a clinical trial has never been reported. This may be because it is an exceedingly rare event and there have not yet been sufficient numbers of patients for such an event to occur. Alternatively, the latency for such an event could be quite long. Since MSCs do not seem to survive in the patients for more than 1 year, the likelihood of malignant transformation of ex vivo processed, transplanted MSCs in patients may be significantly less than envisioned according to the experience with hematopoietic stem cell transplantation [80], gene therapy [81], or predicted from karyotype analysis [79].

We emphasize that the field is relatively young, and definitive conclusions are not yet available; however, current option favors the notion that it is an unlikely outcome and should not impede clinical investigation.

Ectopic tissue formation after systemic infusion

MSCs readily differentiate to osteoblasts, chondrocytes, and adipocytes in vitro which raises the possibility that MSCs may inappropriately differentiate to a mesenchymal tissue, such as bone, after intravenous infusion. A single report of murine MSCs injected into experimentally infarcted myocardium demonstrated calcifications at the site of the cell injection [82]. However, similar findings of ectopic tissue formation have not been reported in countless experimental clinical studies.

Opportunistic infections

Given the remarkable immune modulatory capacity of MSCs, there is concern that MSCs may sufficiently suppress patients' immunity rendering them susceptible to opportunistic infections. Such an outcome has never been reported and MSCs seem to exert differential effects on alloantigen and virus-specific T-cell responses [83] suggesting MSC therapy is unlikely to induce clinically significant increased risk of opportunistic infections.

Clinical applications

MSCs to foster engraftment of HSCs following HCT

MSCs were originally considered to be stem cells comprising the hematopoietic supportive element of the marrow space and were studied in an effort to rebuild the microenvironment to foster HSC engraftment after allogeneic transplantation. The marrow microenvironment is, in fact, damaged by the chemoradiotherapy preparatory regimen which likely disrupts the HSC niche [84] thereby contributing to the delay of hematopoietic reconstitution after both autologous and allogeneic HCT [85,86]. Although, we now recognize that MSCs do not appreciably engraft in the host marrow microenvironment after intravenous infusion; the cells may foster engraftment by immune suppressive mechanisms which could reduce the risk of graft rejection, or facilitate hematopoietic reconstitution by secreting cytokines into the circulation that would promote hematopoiesis reducing the risk of primary graft failure and hasten the time to neutrophil, erythrocyte, and platelet recovery.

The first effort to determine whether MSCs can promote engraftment and hematopoietic reconstitution in patients was reported by Koc et al. in 2000 [87]. Twenty-eight women undergoing autologous HCT with mobilized peripheral blood cells for advance breast cancer were infused with 1 to 2.2 × 10^6 ex vivo expanded MSCs/kg 4 hours before the hematopoietic graft. The MSCs were harvested about a month prior to infusion, before the patients underwent mobilization for stem cell collection, and expanded for 2 to 6 passages. The median time to attain a neutrophil count great than 500/μL was 8 days (range, 6 to 11 days) and a platelet count greater than 20,000/μL was 8.5 days (range, 4 to 19 days). Definitive clinical conclusions cannot be drawn from this single-arm uncontrolled trial, but the rapid hematopoietic recovery demonstrated the potential of MSCs to enhance reconstitution in patients after autologous HCT.

Lazarus et al. assessed the capacity of ex vivo expanded MSCs obtained from HLA-identical sibling donors to facilitate hematopoietic recovery after co-transplantation with either bone marrow or peripheral blood stem cells in patients with hematologic malignancies [88]. MSCs were isolated, expanded, and cryopreserved prior to the initiation of the conditioning regimen. The MSC units were thawed at the bedside and intravenously infused into the patients 4 hours before the hematopoietic cell graft. The median hematopoietic cell doses were 3.6 × 10^8 mononuclear cells/kg for bone marrow and 5.0 × 10^6 CD34$^+$ cells/kg for peripheral blood grafts, while the MSC dose ranged from 1 to 5 × 10^6 cell/kg for both patient groups. Overall, the median time to attain a neutrophil count of 500/μL was 14 days (range, 11 to 26 days) and to a platelet count of 20,000/μL was 20 days (range, 15–36 days). The patients receiving peripheral blood grafts demonstrated a more rapid neutrophil recovery (median, 13.5 days) compared to those receiving bone marrow (15.5 days). While this study also lacked a control cohort of patients, the time to neutrophil recovery of bone marrow appears to be somewhat faster than what is often experienced. On the other hand, it is less clear whether the time to engraftment of PBPC represents a hastening of hematopoietic recovery.

Haploidentical HCT in children typically results in rapid hematopoietic reconstitution, often in as little as 10 days [89]. However, primary graft failure/rejection occurs frequently with these highly T-cell depleted grafts and a second hematopoietic cell infusion is often required. Ball et al. sought to determine whether MSCs could positively impact engraftment in haploidentical children. Fourteen children underwent transplantation with HLA-disparate CD34$^+$ cells obtained from mobilized peripheral blood. A median of 21.5 × 10^6 CD34$^+$ cells/kg were infused. MSCs were isolated from bone marrow about 5 weeks before HCT and expanded up to three passages. The ex vivo expanded cells were infused, either cryopreserved or fresh, at a dose of 1 to 5 × 10^6 cells/kg 4 hours before the hematopoietic stem cell graft. Compared to 47 age-, sex-, and diagnosis-matched historical controls, there was no difference in the time to neutrophil recovery (12 vs. 13 days) or the time to platelet (20,000/μL) recovery (10 vs. 13 days). However, the time to attain a total leukocyte count of 1 × 10^6/μL was shorter in the MSC group (11.5 days) compared to controls (14.9 days, $p = 0.009$). More importantly, none of the children receiving MSCs ($n = 14$) experienced graft failure. In contrast, the graft failure rate among the controls was 15% consistent with the experience of others.

One of the consistent themes of the preclinical studies is that MSCs are most beneficial at limiting doses of HSCs. This observation suggests that umbilical cord blood transplantation may be the most useful setting for MSC co-transplantation. Umbilical cord units must have a threshold cell count for clinical use, as discussed elsewhere in this text, since low cell doses increase the risk of graft failure. Moreover, the time to neutrophil and platelet reconstitution tends to be longer when umbilical cord grafts are used as compared with other HSC sources.

Based on this rationale, Macmillan et al. [90] have co-transplanted parental (haploidentical) MSCs with unrelated umbilical cord blood grafts. Eight patients underwent transplantation with an HLA-matched unrelated umbilical cord graft for a hematologic malignancy. Haploidentical MSCs were isolated from parental bone marrow obtained at the time the patient was referred for transplant and the ex vivo expanded cells were cryopreserved for storage. MSCs, thawed immediately prior to intravenous infusion, were transplanted at a median dose of 2.1×10^6 cells/kg 4 hours prior to the umbilical cord blood graft. The median umbilical cord blood total nucleated cell dose was 3.1×10^7 cell/kg. All patients attained a neutrophil count of 500/μL at a median of 19 days (range, 8 to 28 days) as compared to 86% of historical control patients at a median of 30 days (range, 10 to 59 days). Six of the 8 patients attached a platelet count of 20,000/μL at a median of 1.7 months (range, 1.1 to 3.2 months) compared to 79% of historical controls at a median of 2.7 months (range, 1.5 to 6.6).

Two additional studies of co-transplantation of MSCs with umbilical cord blood cells have been reported [91,92]. However, none were able to show a statistically significant benefit of engraftment or hematopoietic reconstitution; however, this may be due to the small sample size in each study.

Interestingly, Macmillan et al. [90] showed a striking, but not significant reduction of regimen-related toxicity and a corresponding improvement of overall survival. Thus, MSCs may find their greatest application in HCT as a cell therapy to reduce regimen-related toxicity and improve overall survival without directly impacting hematopoietic recovery, consistent with the recent reports that MSCs may confer tissue protection against radiation injury [93,94].

Three studies have used MSCs to rescue HCT patients after graft failure. Le Blanc et al. used MSC therapy to induce hematopoietic recovery in 3 patients with either primary or secondary graft failure [95]. Meuleman et al. rescued 2 of 6 patients [96] and Fouillard et al. reported a single patient in which haploidentical MSCs stimulated autologous hematopoietic recovery after primary failure of a mafosfamide-purged autograft [97]. Collectively, these case reports suggest that MSCs may most significantly foster hematopoietic engraftment/reconstitution under “failure” conditions. Thus, MSCs may find greater value as an agent to rescue graft failure in contrast to up-front use to promote primary engraftment.

Hematopoietic stem cell expansion

Ex vivo expansion of hematopoietic stem cells has been a long sought, but elusive goal. Stem cell expansion would obviate the problem of low stem cell doses which can be problematic in all graft sources; however, most notable in umbilical cord blood transplantation where low cell doses are often limiting and the overall quantity and HLA spectrum of available units is far less than what is currently available among unrelated volunteer donors.

Before MSCs became a cell therapeutic agent, “stromal cells” were used to generate long-term bone marrow cell cultures, which, in principle can be applied clinically to ex vivo expanded hematopoietic progenitors. De Lima et al. recently reported a remarkable clinical outcome employing this strategy [98]. Thirty-one patients underwent HCT using two cord-blood units, one of which contained cord blood that was expanded in ex vivo culture with allogeneic MSCs resulting in a 12.2-fold expansion of total nucleated cells and 30.1-fold expansion of $CD34^+$ cells. Comparing the study patients to patients who underwent standard double-cord blood transplantation, improvements in the time to neutrophil engraftment (15 vs. 24 days, $p < 0.001$), platelet engraftment (42 vs. 49 days, $p = 0.03$), and neutrophil graft failure (12% vs. 47%, $p < 0.001$) were observed. However, these striking results are thought to be due to an expansion of hematopoietic progenitors, but not long-term stem cells. Nonetheless, these data are encouraging and this strategy holds promise to overcome one of the major barriers to umbilical cord transplantation.

MSCs to treat GVHD

The immunomodulatory capacity of MSCs suggests that these cells may be effective agents for the treatment of GVHD. Based on limited preclinical in vitro data, and without animal models, a 9-year-old boy with severe refractory gut and liver GVHD after a matched unrelated donor peripheral blood stem cell transplant was treated with ex vivo expanded MSCs derived from his haploidentical mother [67]. While continuing to receive prednisolone and cyclosporine, an infusion of 2×10^6 MSCs/kg led to a prompt reduction of his serum bilirubin concentration and stool output. His cyclosporine was then discontinued to enhance a graft-versus-leukemia effect, but led to an acute exacerbation of his gut and liver GVHD. A second infusion of MSCs (1×10^6 cells/kg) again resulted in rapid reduction of his serum bilirubin and stool output. About 18 months after the MSC infusions, the patient had recurrent GVHD, developed interstitial pneumonia and died. Although the final outcome of the patient was regimen-related death, this landmark report indicated the potential of MSCs to effectively treat GVHD.

Subsequently, many small studies (case series) have been published which mostly support the notion that MSCs may be effective therapy for GVHD; however, the outcomes are highly varied, possibly due to the different MSC expansion protocols as well as the diversity of patients and treatment schedules. Notably, the growth media supplementation with fetal bovine serum, or human serum platelet lysate, or growth factors with or without serum, may alter the immune modulatory capacity of the processed MSC product.

The largest published trial is a European Group for Blood and Marrow Transplantation phase II multicenter study to treat steroid-resistant acute GVHD [68]. Fifty-five patients (30 adults, 25 children) were enrolled with Grade II ($n = 5$), III ($n = 25$), or IV ($n = 25$) disease whom had previously failed one to five prior therapies. Patients received a median total dose of ex vivo expanded bone marrow MSCs of 1.4×10^6 cells/kg patient body weight (range, 0.4 to 9.0 $\times 10^6$) derived from HLA-identical sibling donor ($n = 5$), haploidentical donors ($n = 18$), or third party HLA-disparate donor ($n = 69$). Twenty-seven patients received one infusion of MSCs, 22 received two infusions, and 6 received three to five infusions, all without MSC-related toxicity. Thirty patients (55%) had a complete response and 9, a partial response (16%) yielding an overall response rate of 71%. HLA-matching had no effect on the response. Importantly, complete responders had a lower 1-year transplant-related mortality compared to partial and non-responders (37% vs.72%, $p = 0.002$) and a higher overall survival (53% vs. 16%, $p = 0.018$). These data portend great utility of MSCs for the treatment of GVHD; however, such remarkable results have not yet been reproduced.

The only large, randomized, double blind, placebo-controlled phase III trial of MSC therapy of steroid-refractory acute GVHD to date was conducted by Osiris Therapeutics, Inc. The study outcome has been released to the public but not published in the peer-reviewed literature. Briefly, patients ($n = 260$, 28 children) received 2×10^6 MSCs/kg or placebo twice per week for 4 weeks. The durable complete response (primary endpoint) was not statistically different between the treatment and placebo groups (35% vs. 30%) and overall survival was not improved; however, the response specifically in the liver (76% vs. 47%, $p = 0.26$ and gut (88% vs. 64%, $p = 0.018$) were significant improved. Although disappointing to the MSC community, our increasing understanding of the effect of prolific expansion and cryopreservation on the immune modulatory capacity of MSCs [99,100] suggests that the cell product tested in this trial was likely not optimal for GVHD therapy. Further biologic studies of ex vivo expanded cells that comprise the clinical MSC product are required to devise superior production protocols yielding MSCs better suited for GVHD therapy.

Future considerations

We have made considerable progress in understanding the highly complex biology of ex vivo expanded MSCs that will undoubtedly foster clinical applications. MSCs hold great promise to reduce the risk of graft rejection and potentially facilitate hematopoietic engraftment reconstitution, especially when the HSC dose is limiting. Additionally, MSCs clearly can modulate the immune response and more definitive evidence of efficacy in the treatment and/or prophylaxis of GVHD is likely to emerge in the not-too-distant future. With our ever increasing understanding of the MSC-immune system interaction, MSCs will likely play a role as adjunct therapy with HCT and possibly as a single cell agent for the treatment of genetic or rheumatologic disorders.

Three great challenges lie ahead. First, we must identify surface markers of MSCs that will and define subsets of cells for specific clinical applications. Second, we must more clearly understand the mechanisms of MSC immune modulation and how to most effectively apply MSCs clinically. Finally, we must conduct numerous pilot clinical trials followed by large, multicenter clinical trials to first demonstrate and then validate the clinical utility of MSCs.

Introduction and history

Hematopoietic stem cells (HSCs) are particularly amenable to *ex vivo* manipulation and have long been considered an attractive target for gene therapy. There are many potential therapeutic applications, including curing genetic diseases, making the hematopoietic system resistant to alkylating agents to allow more effective chemotherapy, and protecting the hematopoietic system from human immunodeficiency virus (HIV) infection. Methods for the genetic manipulation of HSCs evolved from the pioneering efforts of investigators working to establish means for efficient gene transfer to mammalian cells. Initial studies of gene transfer into murine hematopoietic repopulating cells utilized calcium phosphate-mediated transfection of mouse DNA encoding drug-resistance genes into mouse bone marrow (BM) cells [1,2]. The gene transfer efficiency was low in these studies, but they established the potential for HSC gene transfer and the potential for chemoprotection of HSCs.

The development of retroviral vectors allowed for efficient *ex vivo* gene transfer to murine hematopoietic progenitor cells [3] and pluripotent repopulating cells [4–6]. Transduction with retroviruses results in unique, well-defined proviral vector integrants that can be used to track the progeny of individual stem or progenitor cells. Retroviral proviruses were used as markers to demonstrate that self-renewing clones capable of both myeloid and lymphoid repopulation potential could be transduced [4–6]. Two additional prescient predictions were made in these early studies. First, the culture conditions that alter stem cell kinetics may also affect transduction efficiency [5]. Second, retroviral integrants near genes involved in hematopoietic proliferation could alter the phenotype of these stem cells, and retroviral markers might be used to identify nearby genes involved in hematopoiesis, analogous to the use of viruses to identify oncogenes [4]. These studies established the feasibility of gene therapy for hematopoietic disorders by demonstrating gene transfer to HSCs capable of expansion into multiple hematopoietic lineages with persistent transgene expression.

Improvements were made to the retroviral vector systems to reduce the possibility of generating contaminating replication-competent retrovirus in vector preparations, and *ex vivo* gene transfer to large-animal HSCs was attempted. Relatively efficient gene transfer to canine hematopoietic progenitor cells in vitro was achieved [7], but the transduction of repopulating HSCs in large-animal models was inefficient in early studies [8,9]. The first clinical trials evaluated gene transfer to autologous BM collected from acute myeloid leukemia patients or neuroblastoma patients after intensive chemotherapy [10,11]. Long-term gene marking was significantly higher than observed in previous large animal studies, with G418-resistant colonies detected up to 18 months post-transplant at frequencies of approximately 5%. The presence of the retroviral marker in resurgent blast cells of two patients with acute myeloid leukemia demonstrated that infused autologous marrow could be a source of leukemic cells. These studies also demonstrated for the first time in humans that infused gene-modified autologous cells could contribute to long-term hematopoiesis. Subsequent clinical gene transfer studies resulted in lower transduction frequencies, but transduction protocols were refined and the first clearly curative HSC gene therapy was reported 7 years later by Cavazzana-Calvo et al. for X-linked severe combined immunodeficiency (SCID-X1) [12]. This success was then marred by the development of leukemia as a result of insertional mutagenesis and clonal dominance in five out of twenty patients treated in this trial; however, the therapeutic benefits provided by gene therapy still outweighed the risk of leukemia in this patient population [13,14]. Still, myelodysplasia and leukemia have subsequently occurred as the result of insertional mutagenesis in two additional gene therapy trials, one to treat chronic granulomatous disease and the other to treat Wiskott–Aldrich syndrome, both of which used gammaretrovirus vectors to accomplish gene transfer into HSCs[15–17]. These adverse side effects have underscored the need to refine gene transfer protocols for increased safety, resulting in the development of new, safety-modified vector systems and bringing attention to strategies for targeted gene integration and precise gene editing.

Gene transfer vectors

Retroviral vectors

For most HSC gene transfer applications, the goal is to transduce multipotential HSCs and obtain transgene expression in mature hematopoietic cells following expansion and differentiation. Retroviral vectors have been by far the most widely used vectors for *ex vivo* gene transfer to HSCs, due in large part to their ability to integrate efficiently into target cell chromosomes. This allows the integrated vector provirus containing the transgene to be transmitted to all HSC progeny via mitosis during the extensive expansion of HSCs to form the entire hematopoietic system. All retroviruses contain *gag*, *pol*, and *env* genes, replicate using an RNA intermediate, and integrate into the host genome forming a defined provirus structure with two long terminal repeats (LTRs) (Figure 8.1). Integration occurs throughout the host genome but is not random;

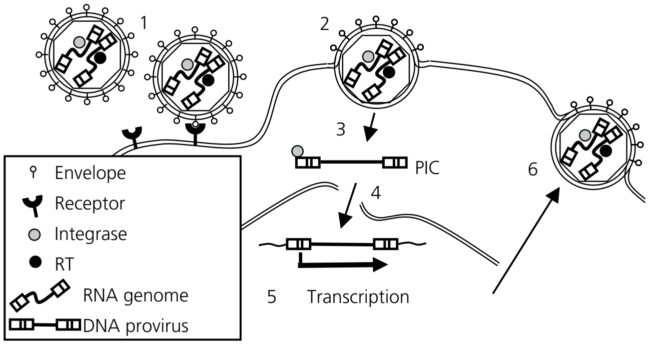

Figure 8.1 Retroviral life cycle. The retroviral virion is composed of matrix, nucleocapsid, and capsid proteins from the *gag* gene that form the virion core containing two viral genomes, and is surrounded by a plasma membrane with incorporated envelope proteins produced from the *env* gene. (1) The envelope protein mediates attachment to the cellular receptor. (2) Fusion of the viral and cellular membranes allows entry of the retroviral core into the cytoplasm. (3) The RNA genome is converted into a double-stranded DNA genome by the viral reverse transcriptase (RT). For foamy retroviruses, this occurs before virus entry. (4) The viral genome and associated proteins, referred to as the pre-integration complex (PIC), must transit to and enter the nucleus. (5) Once in the nucleus, the viral integrase mediates integration of the reverse-transcribed double-stranded DNA viral genome into the host genome. This produces a proviral vector structure with LTRs at each end of the vector genome that form a junction with the host chromosome. The LTRs contain enhancer and promoter sequences to drive viral gene expression. (6) After production of viral proteins and RNA genomes from the integrated provirus, viral cores bud through host cell membranes containing viral envelope to produce new virions.

gammaretroviruses, lentiviruses, and spumaretroviruses each have distinct integration site preferences.

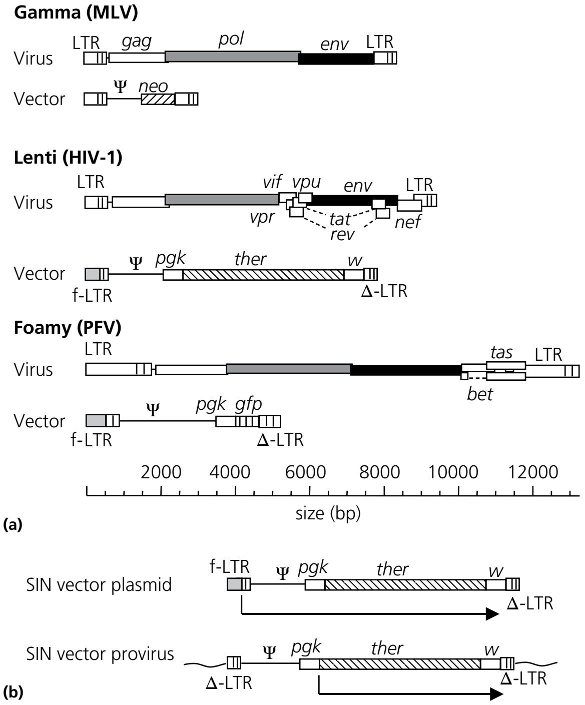

Figure 8.2 Retroviral vectors. (a) Gammaretrovirus, lentivirus, and foamy virus vectors. Schematics for Moloney murine leukemia virus (MLV), human immunodeficiency virus (HIV-1), and primate foamy virus (PFV) are shown, with an example vector schematic below. For each vector, only *cis*-acting regions required for efficient gene transfer are present in the vector, which include the long-terminal repeats (LTRs) and the packaging signal, Ψ. The vectors do not express viral proteins; the structural proteins *gag*, *pol*, and *env* are provided *in trans* (not shown) so the vectors are replication-incompetent. The MLV vector shown expresses a neomycin phosphotransferase reporter gene (*neo*) from the vector LTR. The HIV-1 vector shown expresses a therapeutic transgene (*ther*) from an internal phosphoglycerate kinase (pgk) promoter. Vector transcripts are driven by a fusion LTR promoter (f-LTR) that contains a Rous sarcoma virus promoter with HIV-1 LTR elements. This vector also contains a woodchuck post-transcriptional regulatory element (w) to enhance transgene expression. The foamy virus vector expresses a green fluorescent protein from an internal pgk promoter, and vector transcripts are expressed from a fusion LTR promoter that includes cytomegalovirus promoter elements. (b) Self-inactivating vector design. For the lentiviral vector shown, vector transcripts made during viral vector production are driven by an f-LTR promoter and the 3′ LTR contains a deletion in the U3 region. During reverse transcription, the deleted U3 region of the 3′ LTR is copied to the 5′ LTR of the vector provirus, resulting in an integrated vector with LTRs that are essentially inactive. In the integrated vector provirus, transcription is driven by the internal pgk promoter.

Gammaretroviral vectors

Gammaretroviruses, formerly a subset of the *Oncovirinae* or oncoretrovirus subfamily, are "simple" retroviruses that do not contain accessory genes. Gammaretroviral vectors were the first vectors used for HSC gene transfer and continue to be widely used for many gene transfer applications. To generate vectors, most of the viral structural gene sequences are replaced by the desired transgene(s). LTR sequences and viral *cis*-acting sequences required for efficient incorporation of vector genomes into virions referred to as the Ψ region are retained (Figure 8.2(a)). This results in a replication-incompetent vector where the internal transgene can be expressed either from the viral LTR promoter or from an internal promoter. Vector virions are produced by supplying the viral structural genes *in trans*. Gammaretroviral vectors have evolved from early vectors that contained complete LTR sequences, and could generate contaminating replication-competent viruses by recombination with helper plasmids during preparation, to highly engineered vectors with LTR fusion promoters and "self-inactivating" (SIN) deletions in the LTR (Figure 8.2(b)). Gammaretroviral vector preparations are commonly produced using a packaging cell line where the helper proteins are produced from stably integrated *gag*, *pol*, and *env* genes. This allows facile production of vector-containing supernatants by introducing the desired vector into a packaging cell line (Figure 8.3(a)). An important disadvantage of gammaretroviral vectors for gene transfer to HSCs is that the target cell must be actively dividing for efficient transduction [18]. This is presumably because the viral pre-integration complex requires breakdown of the nuclear membrane during mitosis in order to enter the nucleus [19]. HSCs are quiescent, residing primarily in G_0, so efficient transduction by gammaretroviral vectors requires stimulation into the cell cycle. For *ex vivo* gene transfer, cell cycle stimulation lengthens the culture time and promotes some differentiation, which compromises multipotency, and thus long-term engraftment potential [20].

Lentiviral vectors

Lentiviruses such as HIV-1 are "complex" retroviruses that encode accessory genes in addition to *gag*, *pol*, and *env*. Lentiviral vectors have several advantages over gammaretroviral vectors, including the ability to efficiently transduce quiescent cells [21]. The ability of lentiviral vectors to enter the nucleus independently of mitosis is

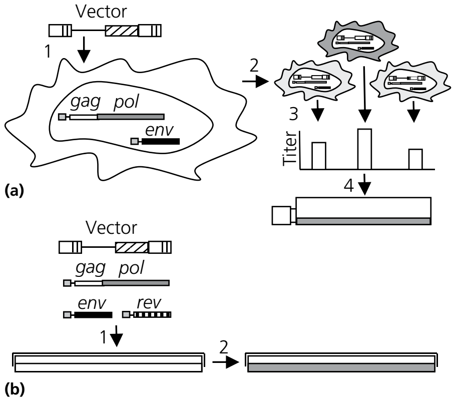

Figure 8.3 Retroviral vector production. (a) Isolating high-titer gammaretroviral producer clones using packaging cell lines. Established packaging cell lines express the vector structural proteins Gag, Pol, and Env. (1) The vector of interest is introduced into the packaging cell line to generate cells with stably integrated vector. The vector can be introduced into the packaging cell lines by transfection of a vector plasmid, or alternatively, if the vector contains a functional LTR, it can be introduced by infection of the packaging cell line with vector virions. (2) Individual "producer" clones are isolated using cloning rings or by limiting dilution. (3) Producer clones are tested to identify a clone that produces vector at high titer. (4) The producer clone is expanded and the producer cell culture medium containing vector virions is collected. (b) Lentiviral vector production by transient transfection. (1) Typically, human embryonic kidney 293 cells are transfected with a plasmid that produces the vector transcript and plasmids that express helper proteins required to form vector virions including Gag, Pol, and an Env pseudotype. (2) Following transfection, the cells are washed and incubated for 24–72 hours, and culture medium containing the vector virions is harvested up to three times during this period.

thought to be responsible for efficient transduction of quiescent cells, but other differences may also be involved [22]. Lentiviral vectors efficiently transduce aphidicolin-arrested cells, demonstrating that they do not require mitosis, but transduction of serum-starved G_0 cells is less efficient. It is now generally accepted that lentiviral vectors require progression of the cell cycle to G_{1b}, likely because reverse transcription is inefficient in G_0 cells [23]. Several groups have shown that efficient lentiviral transduction of repopulating HSCs requires cytokine stimulation supporting this conclusion. SIN lentivirus vectors can be produced at high titers and can efficiently deliver large complex transgenes that reduce the titers of gammaretroviral vectors, such as locus control region-driven globin genes. Most lentiviral vector preparations used for HSC gene transfer have been produced by transient transfection of human embryonic kidney 293 cells. A typical four-plasmid transient vector production scheme is shown in Figure 8.3(b). High titer producer lines have also been developed for lentiviral vectors [24,25].

A disadvantage of lentiviral vectors has been the concern that recombination between vector genomes and viral helper genes may lead to a contaminating replication-competent lentivirus that has some pathogenic properties of the parent virus. Most current lentiviral vector systems have deletions in the viral *tat*, *vpr*, *vpu*, and *nef* accessory genes and have extensive deletion of the viral *env* gene, but do require *rev*. They also have SIN deletions in the LTR including the TATA box. Additional safety measures have been undertaken to reduce the homology between helper and vector sequences by codon optimization, and to reduce the potential for replication-competent recombinants by splitting the Gag and Pol helper functions onto different plasmids [26]. It is thus impossible to generate the wild-type parent virus from the vector and helper plasmids, but concerns remain that a novel replication-competent virus could be generated. To address this, assays have been developed to detect a potential replication-competent lentivirus in vector preparations to be used for clinical applications [27]. Following the development of insertional mutagenesis resulting in leukemia associated with gammaretrovirus-mediated gene transfer in HSCs, lentivirus constructs became the most common gene transfer modality for human HSC gene therapy applications.

Foamy viral vectors

Foamy or spumaretrovirus-based vectors have been developed more recently and have several properties that make them well suited for HSC gene therapy. Foamy viruses have never been shown to cause disease in any host, including humans. They are the largest of the retroviruses at approximately 13 kilobases (kb) and can carry large (at least 9 kb) transgene cassettes efficiently. Foamy viruses are "complex" retroviruses that contain the accessory genes *tas* (formerly called *bel-1*) and *bet*. They infect many host species but are not endemic in human populations, although zoonotic infections can occur. In current foamy virus vectors, there are deletions of the *tas* and *bet* accessory genes and deletions in the LTR, making these vectors SIN. Foamy virus vectors require mitosis for transduction, but they form a stable transduction intermediate capable of being maintained in quiescent cells [28]. This may explain their ability to efficiently transduce hematopoietic repopulating cells with minimal *ex vivo* stimulation [29,30]. Foamy virus vectors are typically produced by transient transfection of human embryonic kidney 293 cells.

Retroviral pseudotypes for HSC gene transfer

Retroviral vectors can be "pseudotyped" at varying efficiencies by substituting a heterologous envelope protein from another enveloped virus for their envelope. This can alter the tropism of the vector to allow transduction of the desired target cell type. The choice of pseudotype is critical for HSC gene transfer as the availability of the receptor on HSCs can affect the transduction efficiency. Early studies showed that the ecotropic envelope of murine leukemia virus-based gammaretroviral vectors allowed for highly efficient gene transfer to murine repopulating cells. However, the human homolog of the mouse ecotropic receptor does not allow for entry via the ecotropic envelope, and the amphotropic envelope receptor is not highly expressed on human progenitor cells [31]. Receptor expression levels can influence the efficiency of gene transfer [32,33] so alternative pseudotypes have been evaluated. The envelope glycoprotein from the vesicular stomatitis rhabdovirus (VSV-G) has been commonly used due to its broad tropism and its ability to allow for efficient concentration by ultracentrifugation. Lentiviral vectors pseudotyped with VSV-G can be concentrated 1000-fold to titers of over 10^9 transducing units/mL and retain most of their infectivity after freezing. Additionally, lentiviral vectors pseudotyped with VSV-G can mediate efficient gene transfer into large-animal long-term repopulating cells. However, there are drawbacks to using VSV-G. VSV-G is toxic, which has limited its use in packaging cells, and human sera can inactivate VSV-G-pseudotyped vectors, which limits *in vivo* delivery. The envelope glycoprotein from cocal virus, a vesiculovirus that causes vesicular stomatitis in animals and is serologically distinct from VSV, efficiently pseudotypes lentiviral vectors. Cocal pseudotyped lentiviral vectors are more resistant to human serum inactivation than VSV-G pseudotyped vectors and efficiently transduce human CD34$^+$ cells that are able to repopulate immunodeficient mice [34].

The feline endogenous virus RD114 envelope has been used for pseudotyping both gammaretroviruses and lentiviral vectors and appears to be more efficient for the transduction of hematopoietic cells than VSV-G when compared at similar multiplicities of infection. The RD114 allows for efficient concentration of both lentiviral vectors and gammaretroviral vectors by centrifugation. A lentivirus that displays a stem cell factor-influenza hemagglutinin fusion in addition to a modified RD114 envelope has shown promise for transduction of human CD34$^+$ cells and allows *in vivo* delivery [35]. This pseudotype is designed to selectively target c-kit$^+$CD34$^+$ cells. The gibbon ape leukemia virus (GALV) envelope has allowed for efficient transduction of long-term repopulating cells in primates [36]. In some cases, pseudotyping can be inefficient, for example when pseudotyping HIV-derived vectors with the RD114 or GALV envelopes. Here, creating chimeric envelopes by substituting the transmembrane or cytoplasmic domain with the corresponding domain(s) from the amphotropic envelope, which does efficiently pseudotype HIV vectors, increases titers. Foamy virus vectors do not normally pseudotype efficiently with VSV-G or with gammaretroviral envelopes due to a specific requirement for interaction between the foamy Gag and Env proteins. Luckily the foamy virus Env allows efficient transduction of large-animal HSCs and also allows concentration by ultracentrifugation. A system has been developed to allow efficient pseudotyping of foamy virus vectors with VSV-G by creating an interaction between the VSV-G and foamy Gag protein using small-molecule controlled dimerization [37].

Envelope glycoproteins from many other viruses such as rhabdoviruses (Chandipura, rabies, and Mokola), filoviruses (Ebola, Marburg, and Lassa), and alphaviruses (Ross River virus and Semliki forest virus), have been used to pseudotype retroviral and lentiviral vectors, but efficient transduction of repopulating HSCs has not been demonstrated using these pseudotypes (reviewed in [38]).

Other vector systems

Adenoviruses are non-enveloped icosahedral viruses that have double-stranded DNA genomes of approximately 30–38 kb pairs and contain fiber projections that mediate attachment and entry. Adenoviral vectors can be produced at very high titers ($\geq 10^{12}$/mL), have a large transgene capacity, and are able to mediate highly efficient gene transfer and gene expression in non-dividing cells. However, most adenoviral vectors have been developed from the Ad5 serotype, which utilizes a fiber that binds the Coxsackie-adenovirus receptor and requires alpha integrins, which are not abundant on hematopoietic cells. Additionally, adenoviruses do not integrate efficiently into the host cell genome, thus gene expression is lost as transduced cells divide and expand. Modified adenoviral vectors have been developed for HSC gene therapy which contain fibers that allow transduction of hematopoietic cells, and contain inverted terminal repeats (ITRs) from adeno-associated viruses (AAVs), which increase the integration frequency [39]. Adenoviral vectors with AAV ITRs that have erythroid-specific transgene cassettes can deliver genes to human cord blood-derived CD34$^+$ cells with transduction frequencies of 5% in erythroid colonies [40].

AAV vectors are derived from helper virus-dependent parvoviruses and can mediate efficient gene transfer to several tissues, particularly liver and muscle. AAV vectors require S phase for efficient transduction, and their transgene capacity is approximately 5 kb, but very high titers can be produced and several different capsid proteins are available to modify the tropism of these vectors. As discussed earlier, the AAV ITRs can mediate integration, but following transduction a large percentage of AAV vector genomes remain in complex episomal forms. There have been reports of transduction of hematopoietic cells with AAV2 vectors, the first AAV vectors developed and the most commonly used, but it has been generally accepted that transduction of hematopoietic cells with AAV2 vectors is inefficient (reviewed in [41,42]). The frequency of gene transfer to rhesus monkey repopulating cells with AAV2 vectors was estimated to be approximately 0.001% [43]. More recently, better AAV2 transduction efficiencies and stable integration has been reported in human hematopoietic cells with long-term repopulating phenotypes in vitro, but has not been demonstrated in large animal models [44]. Improved transduction of mouse HSCs has been reported using AAV1 vectors [45], but large-animal studies have also not yet been reported using this serotype. For both the AAV2 and AAV1 serotypes, second-strand DNA synthesis has been implicated as the rate-limiting step in efficient transduction [45]. Additional AAV serotypes have been evaluated for the ability to efficiently transduce HSCs including serotypes 1, 3, 4, 5, 7, 8, and 10. In the most recent report, serotypes 1, 7, 8, and 10 were all found to be more efficient at transducing murine HSCs in a serial transplant model [45].

Herpesvirus vectors have large genomes (120–230 kb pairs) that can be engineered to carry large transgene cassettes and also have the ability to transduce non-dividing cells. Herpesvirus genomes do not normally integrate but can be maintained episomally or can be engineered to integrate by introducing AAV ITRs. Replication-competent, incompetent, and herpes virus "amplicon" vectors, which are bacterial plasmids that contain only the necessary *cis*-acting regions necessary for replication and packaging, have been developed for various gene therapy applications. Transduction of CD34$^+$ cells has been demonstrated [46].

Non-viral vectors are appealing for HSC gene transfer from the perspective of facile large-scale production and characterization for clinical use. There are many non-viral approaches (reviewed in [47]), but plasmid DNA is typically introduced by electroporation (or more recently nucleofection), by lipid formulation designed to effect delivery into the cytoplasm or by particle bombardment. However, HSCs are difficult to transfect. The main challenges for plasmid gene delivery are achieving efficient delivery of DNA into the nucleus in quiescent cells without significant toxicity from the procedure, and also achieving efficient integration or replication and segregation of episomes during the extensive expansion of HSCs. Efficient non-viral gene delivery to cord blood-derived CD34$^+$ cells has been reported using nucleofection, and electroporation of plasmids that allow for integration via a transposon have been used to mark CD34$^+$ cells, but gene transfer to human CD34$^+$ cells capable of repopulating immunodeficient mice was inefficient [48]. Both the Sleeping Beauty and piggyBac transposon systems have been reported to efficiently transduce human CD34$^+$ hematopoietic cells, allowing for stable, long-term gene expression in a subset of disease models, most notably thalassemia and sickle cell disease, but large animal model utility has yet to be demonstrated (reviewed in [49,50]).

Gene editing and targeted gene integration

Within the past decade, engineered nucleases with designer capacity to alter the DNA sequence cleaved have been developed which make specific genome editing possible. Designer nucleases include transcription activator-like effector nucleases (TALENs), zinc-finger nucleases (ZFNs), and homing endonucleases also referred to as meganucleases. TALENs and ZFNs consist of a nuclease domain fused with a DNA-binding domain to confer sequence specificity, while meganucleases consist of a dual-function recognition and cleavage domain (reviewed in [51,52]). The effect of each of these types of proteins is a double-strand break in the DNA sequence specified, which can result in genetic disruption, reconstitution or editing depending on the DNA repair process, non-homologous end-joining (NHEJ) or homology-directed repair (HDR), which mends the breakpoint. In order to utilize HDR for gene editing and reconstitution, a homologous ectopic template must be provided in addition to the sequence-specific nuclease proteins. One example of targeted disruption in clinical application is a current clinical trial utilizing ZFNs which can target the C-C chemokine receptor 5 (CCR5) locus, a co-receptor for HIV viral entry, resulting in gene disruption and resistance to HIV infection [51]. This strategy recapitulates the functional cure achieved in the "Berlin patient," an HIV$^+$ leukemia patient who received an allogeneic bone marrow transplant from a donor who carried a homozygous mutation in the CCR5 gene following myeloablative chemotherapy [53]. This patient maintained an undetectable HIV viral load after transplant even in the absence of highly active antiretroviral therapy (HAART). While preclinical data suggested this strategy could be applied to HSCs, the current clinical study is testing targeted CCR5 disruption in T cells.

Preliminary data for targeted gene insertion into genomic "safe harbors" exists (reviewed in [51,52]), but has not yet reached clinical study in any cell type (reviewed in [51,52]). Some of the challenges to these approaches include delivery of both nucleases and homologous template sequences to align the break and repair process for the most efficient gene insertion, HDR permissiveness in primary cell types, such as HSCs, and the off-target effects of these nucleases, which could compromise the safety of specific gene targeting.

Gene transfer to HSCs

Source of HSCs for gene transfer

Presently, it is accepted that long-term repopulating, self-renewing HSCs are CD34$^+$ and that isolation of these cells from either mobilized peripheral blood or bone marrow based on CD34 expression allows for efficient *ex vivo* gene transfer of some true HSCs. Furthermore, it is accepted that engraftment of a sufficient number of these cells in an appropriately conditioned host will result in long-term, multilineage hematopoiesis (reviewed in [51]). More refined HSC phenotypes have been identified; however, it remains to be proven whether these populations are able to effectively repopulate and reconstitute hematopoiesis in patients. These populations can include CD34$^+$/CD38$^-$/Rho^{lo} cells [54] or the more complex CD34$^+$/CD38$^-$/CD90$^+$/CD45RA$^-$/CD49f$^+$ cells [55]. One of the largest barriers to clinical implementation of these refined cell subsets for transplantation is the very low numbers of these cells that can be identified and then subsequently purified. Improvements in cell sorting technology may be refined to increase the yield of these true HSCs, but will likely require *ex vivo* expansion techniques to provide cell numbers that are clinically effective in transplantation.

Manipulating a mouse donor using chemotherapy with 5-fluoruracil can improve the transduction efficiency of murine BM-derived HSCs [4]. BM recovering from 5-fluoruracil treatment is enriched for cycling early progenitors and stem cells, which likely explains the efficient transduction with gammaretroviral vectors. In large-animal models, the cytokine granulocyte colony-stimulating factor (G-CSF) alone or in combination with stem cell factor (SCF) is commonly used to prime BM, or to mobilize primitive repopulating stem cells into the peripheral blood prior to collecting target cells for gene transfer. However, SCF is unavailable for clinical use in the United States due to anaphylactic reactions in some patients, so G-CSF alone has also been evaluated as a priming/mobilizing cytokine.

Hematti et al. observed low transduction frequencies in rhesus macaques with gammaretroviral vectors using G-CSF-mobilized peripheral blood cells [56]; however, efficient gene transfer was observed in the baboon model using G-CSF-mobilized cells when gammaretroviral vectors were produced with a GALV pseudotype in human 293 packaging cells [36]. More recently, AMD3100, a CXCR4 antagonist, has been used for highly efficient mobilization. AMD3100 reversibly blocks the interaction between the chemokine receptor CXCR4 and its ligand SDF-1α which plays an important role in regulating stem cell mobilization. In the rhesus macaque, cell-cycle analysis of AMD3100-mobilized CD34$^+$ peripheral blood cells shows that these cells have significantly fewer cells in G_0 (31%) compared with G-CSF-mobilized cells (79%), and significantly higher numbers in the G_1 phase [57]. Additionally, a higher percentage of AMD3100-mobilized cells expressed CXCR4 and were able to migrate towards the CXCR4 ligand SDF-1α in vitro, suggesting they may have improved homing ability. In this study, *in vivo*-gene-marking levels with a gammaretroviral vector were higher for AMD3100-mobilized cells than for G-CSF-mobilized cells. A comparison of the ability of AMD3100 and G-CSF-mobilized patient CD34$^+$ cells to repopulate immunodeficient mice also showed improved engraftment. These studies serve to illustrate the importance in selecting the source of cells and the vector pseudotype for efficient HSC gene transfer, as the phenotypes of target cells can vary significantly.

Cord blood is another promising source of HSCs for gene transfer, although the low number of repopulating cells that can be harvested has limited its utility for application in adults. Most gene transfer experiments in large animals and humans use CD34$^+$ cells isolated using magnetic beads coupled to an anti-CD34 antibody. While more refined cell surface marker expression has been reported to elucidate the true long-term repopulating HSC [55], separation techniques are not yet available to isolate cells with these complex phenotypes in scale for preclinical transplantation beyond small animal models.

Ex vivo culture conditions

During *ex vivo* culture, the objective is to stimulate the target cells into the cell cycle to increase gene transfer efficiency while maintaining their engraftment and long-term repopulating ability. Conditions for efficient transduction of murine HSCs were established over 20 years ago, but these conditions were not effective for large-animal studies or for clinical trials. *Ex vivo* conditions for efficient gene transfer to large-animal repopulating cells have more recently been developed by experimentation with different cytokine cocktails and by employing CH-296 fibronectin fragment [58]. CH-296 (RetroNectin®) is a modified recombinant 639 kDa human fibronectin fragment that contains the fibronectin cell-binding and heparin-binding domains, and enhances transduction of HSCs with gammaretroviral, lentiviral, and foamy virus vectors. The enhancement is believed to occur as a result of co-localization of vectors and target cells, at least for gammaretroviral vectors, as well as from inhibiting apoptosis of repopulating cells during *ex vivo* culture [59] and increasing engraftment [60]. Many cytokine cocktails have been used (reviewed in [61]), and for large-animal studies SCF, G-CSF, megakaryocyte growth and development factor (MGDF), fms-like tyrosine kinase ligand (Flt3-ligand), interleukin

(IL)-3, and IL-6 are commonly used with CH-296. The use of IL-3 has been shown to reduce the engraftment capability of murine HSCs [62], but IL-3 has been used in cytokine cocktails for high-level gene transfer in primate models and in clinical studies. For lentiviral and foamy virus vectors, efficient gene transfer to long-term large-animal repopulating cells has been demonstrated with minimal *ex vivo* culture, as short as 18 hours. For gammaretroviral vectors, efficient transduction of large-animal repopulating cells typically requires a prestimulation period of at least 24 hours, and a total *ex vivo* culture time of 72–96 hours, presumably due to the fact that gammaretroviral vectors require mitosis and are more labile than lentiviral or foamy virus vectors in quiescent cells [28]. The media in which CD34$^+$ cells are cultured for clinical applications requires minimal animal-derived components. There are several commercial media available which are marketed to preserve HSC viability and even promote HSC expansion, as well as meet good manufacturing practice requirements for use in the gene transfer process for clinical application. Varied degrees of success in clinical trials have been reported with each media formulation and completely animal-product-free media are currently being investigated for preclinical utility.

In vitro assays for HSC gene transfer

In vitro assays have limited use for predicting gene transfer efficiency to true long-term repopulating cells but are essential tools for vector development. Hematopoietic cell lines are useful for establishing the tropism of novel vectors and pseudotypes, and also for establishing the specificity of lineage-restricted promoters. When combined with methods such as flow cytometry to elucidate specific cell lineages, the composition of the gene modified population can be better elucidated, but there is currently no evidence to support that this information provides valuable insight into engraftment within specific hematopoietic compartments. Long-term culture initiating cell assays can be used as a surrogate assay for gene transfer to repopulating cells, but more commonly gene transfer into hematopoietic progenitors is determined using colony-forming unit assays. Cells enriched for hematopoietic progenitor cells are isolated and exposed to vector before being plated in semi-solid media with cytokines that allow for the development of myeloid and erythroid hematopoietic colonies. Colony-forming unit assays allow evaluation of the transduction efficiency of immature hematopoietic cells, but also indicate whether gene expression has been maintained during expansion of the individual progenitor cells into a colony. In some cases, mosaic transgene expression is observed, which can indicate delayed integration. Low-level gene expression in colonies, with loss of transgene expression over time in parallel liquid cultures, indicates transient gene expression, commonly observed when using non-integrating vectors, or as a result of pseudotransduction. Pseudotransduction is the transfer of protein present in the vector preparation to target cells [63], which can be a problem, particularly when using concentrated vector preparations. Furthermore, individual colony assessment for number of retrovirus integrations can yield informative data on the average number of vector insertions (copy number) in repopulating cells. This information is useful in determining the optimal conditions to balance efficient gene transfer with safety, as multiple integration events increase the risk of insertional mutagenesis as discussed further later.

Gene transfer to mouse HSCs

Mice continue to be useful for developing methods for efficient gene transfer to HSCs due to their relatively low cost. Typically, BM cells are isolated from the femurs of donor mice, enriched for HSCs by depletion of cells with defined lineage markers expressed on the cell surface, exposed to vector, and reinfused by tail vein or intrafemoral injection into lethally irradiated congenic recipients. Mouse repopulating cells that give rise to long-term multilineage reconstitution and self-renewal can be highly purified by fluorescence-activated cell sorter by removing cells with lineage (Lin) markers (CD3, CD4, CD5, CD8, Ter119, B220, Gr-1, and Mac-1 can be used) and collecting cells that express Sca-1 and c-kit markers. Purified mouse Lin$^-$Sca-1$^+$c-kit$^+$ cells, or “LSK” cells, contain virtually all the repopulating ability, but selecting Thy1.1^{lo} and Flk2$^-$ cells can be used to further enrich for stem cells. After transplantation, donor cells are commonly detected using the Ly5 allele, which is expressed on the cell surface (also known as CD45 or protein-tyrosine phosphatase receptor, type c) and can be detected by flow cytometry. Stable gene transfer to pluripotent HSCs with self-renewal capability can be demonstrated by analyzing integration sites in secondary recipients [5]. Mouse models are commonly used to develop improved methods for HSC purification and *ex vivo* transduction [64], to study methods for *ex vivo* expansion of HSCs [65], and more recently to compare the genotoxicity of viral vectors due to insertional mutagenesis [66]. Some disease candidates for gene therapy, including Fanconi anemia, lack large animal models in which to assess the efficacy of gene transfer strategies, thus mouse models provide the best therapeutic analysis for gene therapy in these settings. With the development of xenotransplantation mouse models to assay gene transfer into human hematopoietic cells, an increasing number of studies are now performed in immunodeficient mouse models. For diseases such as SCID, where large animal models exist, the use of immunodeficient mouse models has provided an inexpensive and more rapid means to evaluate safer gene transfer modalities before proceeding with large animal preclinical testing [67]. Furthermore, the recent development of humanized mice by reconstitution of immunocompromised mouse model with human CD34$^+$ cells has allowed for additional disease modeling, specifically for HIV infection, allowing *in vivo* gene therapy strategies to be evaluated [68,69].

Immunodeficient xenotransplant mouse models

The SCID-hu mouse [70], the SCID mouse [71], and the immunodeficient BNX (B is beige or reduced natural killer (NK) cell number, N is nude or athymic, and X is X^{id}, which reduces lymphokine-activated killer cells) mouse [72] xenograft models set the stage for studies aimed at improving gene transfer to the human hematopoietic cells. The human cells that repopulate immunodeficient mice, now commonly referred to as SCID repopulating cells or SRCs, were found to be distinct from hematopoietic progenitors assayed in vitro and were relatively refractory to transduction with gammaretroviral vectors [73]. Efficient transduction of SRCs with gammaretroviral vectors was obtained by stimulating human CD34$^+$ cells with cytokines and extending the *ex vivo* culture time [74]. Conversely, efficient transduction of SRCs with lentiviral and foamy virus vectors can be obtained with minimal *ex vivo* culture [29,75]. An early study by Ferrari et al.[76] used the BNX mouse to demonstrate functional correction of human adenosine deaminase (ADA)-deficient patient cells using a retroviral vector. Further refinements to immunodeficient mouse models, such as deletion of the IL-2 common γ chain (NOG and NSG mice, (reviewed in [77]) have allowed for robust engraftment of both myeloid and lymphoid cells using low numbers of transplanted human cells [78] and have more recently resulted in a “humanized” mouse, recapitulating a functional immune system capable of modeling human immunodeficiency virus infection (reviewed in [79]). However, all mouse models are restricted by a short life span and a limited proliferative-demand placed on the transplanted cells. Long-term hematopoietic potential can be evaluated with the use of serial transplantation into secondary recipients, but as this requires removal of the cells from the primary host environment and re-engraftment into a subsequent niche, it is not an accurate representation of long-term engraftment and hematopoiesis.

A comparison of baboon repopulating cells with baboon SRCs using the same source of retrovirally marked CD34$^+$ cells showed that SRC engraftment did not correlate with long-term engraftment in the baboon [80]. In this study, a comparison of the individual clones that repopulated the baboons and the SRCs revealed common proviral vector integrants at 6 weeks but not at 6 months after transplantation. These results suggest that distinct hematopoietic stem/progenitor cells are responsiblefor hematopoietic reconstitution in immunodeficient mice compared with non-human primates. Thus, while immunodeficient mouse models are useful for improving gene transfer techniques to HSCs, transduction frequencies in SRCs may not correlate to frequencies observed in human and large-animal long-term repopulating cells.

Gene transfer to large-animal repopulating cells

Long-term marking frequencies obtained in gene transfer experiments in large-animal models such as canines and monkeys have more accurately predicted gene transfer frequencies obtained in clinical trials than have mouse studies. This is likely due to similar stem cell kinetics, as discussed earlier, and the fact that the cytokines used in these models during *ex vivo* transduction protocols have higher identity to human cytokines and thus also more similar function. Gene transfer to long-term repopulating cells in large animals models was initially difficult to achieve (reviewed in [81]), but more recently efficient gene transfer has been observed using improved protocols with CH-296 fibronectin fragment [82], typically used with a cytokine cocktail that includes SCF, MGDF, and Flt3 ligand, and may also include G-CSF, IL-3, and IL-6. With sufficient *ex vivo* prestimulation and culture time, gammaretroviruses can now be used for stable polyclonal gene transfer to primate long-term repopulating cells at frequencies of 10–25% and in one case 60% in the peripheral blood.

Gene transfer into baboons and rhesus macaques using HIV-derived lentiviral vectors has been inefficient, presumably due to post-entry restriction by Trim5α [83]. Hanawa et al. have achieved high levels of multilineage gene marking (average 18%) into rhesus macaques using simian immunodeficiency virus-derived lentiviral vectors [84], which are not restricted by rhesus Trim5α. Similar gene transfer frequencies have been obtained using HIV-derived lentiviral vectors into pigtailed macaques (*Macaca nemestrina*), which are permissive for HIV-based lentiviral transduction [85,86]. In these studies, amphotropic (simian immunodeficiency virus)- and VSV-G (HIV)-pseudotyped lentiviral vectors gave similar marking efficiencies with *ex vivo* culture times of 72 hours and 48 hours, respectively.

The limiting factor(s) for HSC transduction is unclear in these large-animal experiments, but it is interesting to note the similar transduction efficiencies using lentiviral vectors pseudotyped with the retroviral amphotropic envelope or with VSV-G. Transduction in the presence of CH-296 allows saturation of the amphotropic vector in human CD34$^+$ cells in vitro [87], so it will be of interest to determine whether transduction efficiencies can be further increased by combining vectors with different pseudotypes. Efficient polyclonal multilineage gene transfer to canine repopulating cells has been achieved using lentiviral vectors [88] and foamy virus vectors [30] using an even shorter 18-hour *ex vivo* culture protocol. In summary, efficient gene transfer to large animal repopulating cells can be achieved with gammaretroviral, lentiviral, or foamy retroviral vectors. However, for lentiviral and foamy virus vectors, rapid *ex vivo* transduction protocols can be employed, which may enhance engraftment.

Most notably, non-human primate models can now be used to model HIV treatment by use of a hybrid HIV/simian (S)IV virus referred to as “SHIV.” The ability to study HSC biology and transplantation in this model with an intact immune system has enabled pioneering work in HIV/AIDS gene therapy [89,90]. The use of this specific large-animal model is particularly important for these studies because the level of gene-modified HSC engraftment and lymphoid reconstitution significantly influences therapeutic benefit when anti-HIV infection strategies are employed.

In vivo delivery of transgenes to HSCs

The ability of hematopoietic cells to efficiently home to the BM and provide lifelong hematopoiesis has helped to establish *ex vivo* transduction as the most common method for gene transfer to HSCs. However, direct injection of vector preparations into recipients may be particularly advantageous for diseases such as Fanconi anemia, in which *ex vivo* manipulation of HSCs is problematic due to their fragility, as well as infectious diseases such as HIV, since expensive and complex mobilization, collection and *ex vivo* transduction approaches are costlyand not readily mobile. Additional advantages are that enrichment and *ex vivo* culture of HSCs, which are expensive for large-animal and clinical studies, are not required, and loss of engraftment ability due to *ex vivo* culture may be avoided. Direct intrafemoral injection of lentiviral vectors pseudotyped with VSV-G results in low but persistent transduction levels in mouse HSCs [91], but VSV-G pseudotyped vectors are inactivated by human sera, so for clinical *in vivo* applications, alternate pseudotypes, such as Cocal, or alternate vector types, such as foamy virus, will be important.

Ravin et al. evaluated the intravenous delivery of RD114-pseudotyped gammaretroviral vectors into 3-day-old SCID-X1 dogs [92]. In this model, gene-modified repopulating T cells have a selective advantage, and therapeutic levels of corrected T cells were achieved in three of four dogs. Therapeutic levels of T cells were not achieved in the dog that was administered the lowest dose of vector; the level of corrected T cells was very low and a limited number of clones was present. Surprisingly, in this study, a significant number of gene-modified B lymphoid and myeloid cells were observed. Since these cells are not expected to have a selective advantage, this suggests that gene transfer was relatively efficient. It will be interesting to determine whether *in vivo* delivery can be used to efficiently transduce HSCs in large-animal models and to determine whether lentiviral vectors have an advantage for *in vivo* delivery to HSCs, which are considered to be quiescent.

Expansion of gene-modified cells prior to infusion

Ex vivo expansion of long-term repopulating cells prior to or during transduction could increase the number of infused cells and thus increase the engraftment of gene-modified cells. Infusion of a higher number of stem cells would more efficiently compete with endogenous stem cells so less conditioning and potentially less toxicity would be required. This would be especially important for genetic and infectious diseases, in which only a reduced-intensity conditioning may be possible. Although self-renewal has been demonstrated *ex vivo*, attempts to expand long-term repopulating cells with cytokine cocktails have only allowed for modest increases in HSCs.

Another approach is to more directly manipulate pathways involved in stem cell maintenance or expansion such as homeobox proteins, or Notch and Wnt signaling proteins. Homeobox, or Hox, genes regulate differentiation during embryogenesis; *HoxB3* and *HoxB4* are preferentially expressed in BM cells that are highly enriched for primitive cells. Expression of *HoxB4* from a gammaretroviral vector resulted in a 40-fold increase in mouse HSCs [93], and a Tat–HoxB4 fusion protein has been developed for *ex vivo* applications to avoid potential genotoxicity from permanent *HoxB4* expression. The Wnt and Notch pathways are involved in stem cell maintenance and self-renewal. Wnt proteins and Notch ligands have also been used to expand repopulating cells, but the level of expansion observed was less dramatic.

More recent efforts to expand HSCs have included factors such as pleiotrophin [94,95], prostaglandin [96,97], and the combination of angiopoietin-like 5 and insulin-like growth factor [98]; however, the most notable *ex vivo* expansion of CD34$^+$ hematopoietic cells was supported by addition of the aryl hydrocarbon receptor antagonist, StemRegenin 1 (SR1) [99]. However, the engraftment of HSCs expanded by any of these methods in patients is currently unknown. Furthermore, it is believed that a combination of methods will most likely produce the most therapeutically effective *ex vivo* HSC expansion. The combination of Notch pathway modulation and SR1 is currently being clinically investigated, but likely will better define effects on short-term reconstitution rather than long-term hematopoiesis (reviewed in [51]).

Expansion of gene-marked cells *in vivo*

Increasing the percentage of gene-modified repopulating cells post-transplant using *in vivo* selection could expand the potential of HSC gene therapy to hematopoietic diseases, such as thalassemias, and infectious diseases, such as HIV, which require relatively high levels of gene transfer [100]. Positive selection of cells post-transplantation has been demonstrated using a method in which drugs that bind to and dimerize a modified receptor molecule transgene transmit a growth signal to the cell [101]. The small-molecule drugs are called chemical inducers of dimerization, and the receptors are modified to remove their extracellular domain and to contain binding regions for their small-molecule ligands. To date, this approach has been limited in that receptors capable of expanding HSCs have not been identified.

Negative selection using alkylating agents that are toxic to stem cells such as 1,3-bis-(2-chloroethyl)-1-nitrosourea (BCNU) or temozolomide can be performed to expand gene-modified stem cells that are protected by a mutant O6-methylguanine-DNA methyltransferase (*MGMT*) transgene [102]. In this approach, the drug O6-benzylguanine inactivates endogenous MGMT protein but not the mutant MGMT protein. Following *ex vivo* gene transfer of the mutant *MGMT* transgene to HSCs, treatment with BCNU and O6-benzylguanine is toxic to cells that did not receive the *MGMT* transgene and results in expansion of gene-modified cells. This approach allows for the durable expansion of repopulating cells in large-animal models (Figure 8.4), demonstrating that selection occurs in very primitive cells (reviewed in [103]). *MGMT*-mediated selection might be used for gene therapy of hematopoietic diseases, such as thalassemias, by including therapeutic globin and *MGMT* transgenes together in a bicistronic vector. Gene transfer of *MGMT* to HSCs can also be used to protect the hematopoietic system from high-dose chemotherapy during treatment for solid tumors or leukemias. Early clinical studies explored the use of the multidrug resistance gene *MDR-1* for this purpose, but the marking was very low and *in vivo* selection was not observed. More recently, a clinical study to evaluate chemoprotection of the hematopoietic system using *MGMT*-mediated selection in poor-prognosis glioblastoma patients reported increased survival and hematopoietic chemotherapy resistance after combination chemotherapy including O6-benzylguanine and temozolomide [104]. In this study, a gammaretroviral vector was used to transfer a mutant *MGMT* to G-CSF-mobilized patient CD34$^+$ cells *ex vivo* and single agent BCNU was administered as a chemotherapy for treatment of the brain tumor and as conditioning prior to infusion of the gene-modified cells after a <96-hour culture and transduction period. Following recovery from BCNU-induced myelosuppression and engraftment of the mutant *MGMT*-expressing CD34$^+$ cells, patients began receiving 28-day cycles of temozolomide, the standard chemotherapy treatment for glioblastoma, in combination with O6-benzylguanine. Transient increases in gene-modified cells in the peripheral blood of these patients were observed after each chemotherapy cycle, in concert with mild myelosuppression as a result of chemotherapy. However, the number of gene-modified colony-forming cells in each patient increased over time and with chemotherapy, suggesting that selection at the stem/progenitor cell level was achieved with this regimen *in vivo*. While two of three patients retained gene-modified cells at levels greater than 35% of peripheral blood white blood cells for the duration of the study, a third patient with relatively low levels of gene-modified cells lost gene marking after 9 cycles of combination chemotherapy approximately 10 months after transplantation. This suggests that chemoselection may induce clonal exhaustion if a small number of HSCs are available to contribute to hematopoiesis. However, large-animal studies of the same mutant *MGMT* have not resulted in loss of gene-modified cells over time and have also demonstrated long-term *in vivo* selection of gene-modified colony-forming and peripheral blood white blood cells, to

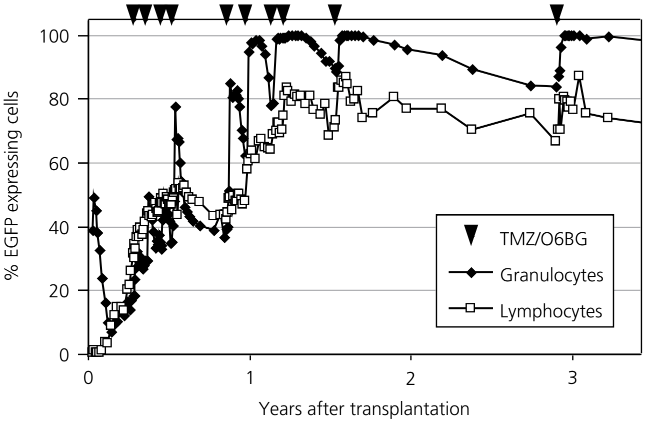

Figure 8.4 *MGMT*-mediated *in vivo* selection. A dog was transplanted with autologous CD34$^+$ cells transduced with a gammaretroviral vector expressing the P140K mutant MGMT and enhanced green fluorescent protein (EGFP). After hematopoietic reconstitution, *in vivo* selection was achieved using a series of chemotherapy treatments with the alkylating agent temozolomide (TMZ) and the MGMT inhibitor O6-benzylguanine (O6BG). Stable increases in gene-modified granulocytes and lymphocytes indicate selection of primitive long-term repopulating cells.

high levels (>80%), even when initial gene marking was low (<5%) [86]. Most of these animals received O6-benzylguanine in combination with BCNU, rather than temozolomide. It is postulated that this difference in selection kinetics between BCNU and temozolomide results from the type of cytotoxic DNA damage induced by each individual agent, and the number of cell divisions required to produce a cytotoxic effect. This suggests that BCNU-induced DNA damage is more cytotoxic to HSCs when given in combination with O6-benzylguanine.

Another strategy to mediate *in vivo* selection of gene-modified cells is through knockdown of the hypoxanthine ribosyl transferase (HPRT) gene with expression of an interfering RNA [105]. Purine analogs such as 6-thioguanine (6TG) and 6-mercaptopurine (6MP), which have been used in the treatment of leukemia, are converted to fraudulent purine nucleotides which can be incorporated into DNA during cell division, causing mismatch repair pathway activation, cell-cycle arrest, and initiation of apoptosis. Conversion of these purine analogs to their bioactive, cell-death-initiating forms requires HPRT function. Thus, by including an HPRT-specific interfering RNA within a transgene cassette, cells expressing the gene modification will be resistant to the effects of 6TG and/or 6MP. The primary toxicity of these purines is myelosuppression, although some patients have also experienced hepatotoxicity from 6TG treatment [106]. Extensive clinical use of these oral drugs has demonstrated that they are tolerated for long periods of time and can be titrated to achieve optimum hematologic toxicity. Preclinical studies in murine HSCs have demonstrated that lentivirus-mediated delivery of an interfering RNA-mediated purine analog (iPAR) to knockdown HPRT expression resulted in 6TG resistance in transplanted mice [105]. When treated with 6TG, these mice demonstrated increases in iPAR gene-modified cells in both peripheral blood and bone marrow; however, prolonged treatment of 6TG was required to elicit the selection (2 cycles consisting of daily administration over 15 of 21 days with a 2–3 week break in between cycles), and stability of HSC selection was monitored to only 5 weeks after the second cycle. Furthermore, the level of gene-modified HSC maintenance was wildly variable in the mice treated (range 0–44.8% of HSCs) and no clonal analysis was performed to rule out oligoclonal expansion as a cause for the observed selection *in vivo*. Still, considering the known carcinogenicity of alkylating agent chemotherapy, this strategy could provide a less toxic alternative to achieve levels of gene marking required for therapeutic benefit in some patient populations.

Immune responses to transgenes

In many situations, the transgene delivered to HSCs will be foreign, and there is the potential for an immune response to gene-modified hematopoietic repopulating cells. In gene-marking studies, a foreign protein such as neomycin phosphotransferase or green fluorescent protein has been expressed in HSCs and their progeny. In cells that express these proteins, they can be processed and presented through MHC class I and II pathways and can trigger cytotoxic, helper, and memory T-cell responses. Processed peptides from green fluorescent protein have been shown to elicit T-cell immune responses in transplanted mice, baboons, and rhesus macaques. Immune responses can also be a problem for clinical applications where a patient may express a truncated form of the therapeutic transgene or may not express the transgene at all. In these cases, the immune system may recognize the therapeutic transgene as foreign. This has been observed in a canine preclinical model for Hurler syndrome, where a strong humoral response was associated with a loss of *in vivo* repopulating cells [107]. In settings where a myeloablative pre-transplant conditioning regimen will be used, pre-existing immune cells are eliminated and a state of tolerance to the foreign transgene can be established. However, even when high-intensity conditioning has been used, cytotoxic T cells specific to a foreign antigen have been observed [108]. Cyclosporine has been used successfully to inhibit the development of immune responses in canines after transplantation of gene-modified cells. Immune responses are not expected to occur in clinical gene therapy situations where there are severe pre-existing immunodeficiencies such as for SCID-X1 and no immune responses have been reported to date in any clinical trial utilizing autologous gene-modified HSCs as discussed later.

Clinical trials of HSC gene transfer

Early studies

The first clinical HSC gene-marking studies demonstrated that persistent gene marking could be obtained in human repopulating cells [10,11]. Early therapeutic clinical trials attempting to transduce HSCs were performed using the multidrug resistance gene *MDR-1* [109–111]. The product of the *MDR-1* gene, P-glycoprotein, is an energy-dependent drug efflux pump that reduces the intracellular concentrations of a wide range of drugs and xenobiotics including chemotherapy agents such as etoposide. The approach was to protect the hematopoietic system from the dose-limiting myelosuppressive effects of chemotherapeutic agents used to eradicate tumors. In these studies, the gene transfer rates were very low, less than 1 in 10^4 cells, similar to earlier studies in the canine and primate models. Additional early clinical HSC gene transfer studies demonstrated low-level but persistent gene marking for ADA-SCID [112,113] and Gaucher disease [114], but therapeutic benefit was not achieved.

In 1995, a report commissioned by the National Institutes of Health concluded that the low efficiency of gene transfer suggested that more emphasis be put on basic aspects of gene transfer, novel vector development, and the study of stem cell biology, but that there was a clear and legitimate need for clinical studies to evaluate various aspects of gene therapy approaches [115]. Improvements to HSC gene transfer were made and several clinical studies were undertaken, including trials for Fanconi anemia [116], leukocyte adhesion deficiency [117], and acquired immune deficiency syndrome [118], but with no clear therapeutic benefit. To date, clinical trials for gene transfer to HSCs have used gammaretroviral and lentiviral vectors. Foamy virus vectors are being pursued preclinically with increasing interest, but currently no foamy virus vectors have been approved for use in an interventional gene therapy clinical trial. Table 8.1 summarizes recent clinical trials for HSC gene transfer.

Genetic diseases

Severe combined immunodeficiency syndrome (SCID)

More than two decades of clinical research in HSC gene therapy for SCID have been conducted, including X-linked and adenosine deaminase (ADA) deficient SCID syndromes, and these have provided a wealth of information which has exponentially stimulated the development and improvement of gene therapy strategies for other diseases. A large international effort beginning in France and involving a total of five clinical trials, treated more than 50 patients, 20 with X-SCID and at least 30 with ADA-SCID [12,119–123] with over 13 years of follow-up in the first patients treated.

Immunodeficiency has been corrected in 85% of the X-SCID patients and >70% of the ADA-SCID patients and only two patients, both X-SCID, have died. As noted earlier, the success of these studies was hindered by the development of leukemia in five of the X-SCID patients treated, all of whom developed uncontrolled clonal T-cell expansion as a result of the gene transfer and deregulated expression of proximal oncogenes nearby to the site of gene integration. One of these patients died as a result of the leukemia, but the other four patients were cured with standard therapy. However, over the next 5 years, follow-up demonstrated 36 SCID patients who benefitted clinically from these studies, outweighing the hesitation to continue development of this approach. Furthermore, results obtained from the analyses of clonal repertoires in all patients treated have provided a valuable tool for investigating *in vivo* hematopoiesis. Each disease and the associated clinical studies are described in the following sections.

SCID-X1

The first clearly therapeutic HSC gene therapy trial was reported for SCID-X1 [12,124], which is caused by mutations in the common cytokine receptor γ chain (γc, *IL2RG* locus), resulting in the absence of mature T lymphocytes and NK cells. Corrected SCID-X1 lymphoid progenitors have a strong selective advantage due to the restoration of survival and proliferation signals mediated by the γc receptor. Patients with no HLA-identical siblings were eligible for the study and, due to the immunodeficiency, no pretransplant conditioning was given. Autologous CD34$^+$ cells transduced with a gammaretroviral vector pseudotyped with the amphotropic envelope were used. Of the initial 10 patients treated, T-cell development occurred in nine, and T cell reconstitution correlated with the dose of CD34$^+$ cells infused [12]. In these studies, small numbers (1%) of transduced myeloid cells were detected, and analysis of vector integration sites by linear amplification-mediated PCR demonstrated polyclonal T-cell repopulation and transduction of primitive multipotential progenitors with self-renewal capacity [125]. An additional four patients were successfully treated by Gaspar and colleagues in the UK using a gammaretroviral vector pseudotyped with the GALV envelope [121]. These authors recently reported that, of a total of 10 patients now treated, six had restoration of immune function with no requirement for prophylactic immunoglobulin replacement [126]. The success of these studies was attributed in part to the improved transduction methods for gene delivery into CD34$^+$ cells, which included CH-296 and cytokine cocktails that included SCF, MGDF, IL-3, and Flt3 ligand. For both studies, the T-cell repertoire was diverse, and T-cell receptor excision circle (TREC) analysis identified naïve T cells long after transplantation, even in the absence of marked myeloid cells. Thus, a gene therapy approach may allow for better long-term thymopoiesis than is observed with HLA-identical and haploidentical allogeneic transplantation, in which hematopoiesis remains of host origin in the absence of pretransplant conditioning [127].

In two older patients treated at 15 and 20 years of age, SCID-X1 gene therapy failed [128]. In both patients, there was efficient gene transfer to CD34$^+$ cells in vitro, and in one patient there were similar marking levels in B, NK, and myeloid cells to patients less than 1 year old who were successfully treated. Chinen et al. investigated gene therapy as a salvage treatment for three patients aged 10, 11, and 14 years who had previously received T-cell-depleted BM transplants from a parent, but had incomplete immunologic reconstitution with frequent infections and chronic diarrhea [129]. In this study, G-CSF mobilized peripheral blood CD34$^+$ stem cells were transduced with a GALV-pseudotyped gammaretroviral vector expressing γc and infused without prior conditioning. All three patients had detectable retroviral marking in myeloid and lymphoid lineages to at least 12 months post-transplant. The 10-year-old patient had relatively high gene marking in T cells consistent with a strong selective advantage in this lineage. In this 10-year-old patient, CD4$^+$ and CD8$^+$ counts increased, and CD4$^+$CD45RA$^+$ naïve cells and TRECs persisted, indicating restoration of thymic function. Vβ spectratype analysis showed increased T-cell receptor diversity. Thus, a clear therapeutic benefit could be established in this patient, and the authors noted that in addition to the younger age, this patient also had previous full T-cell reconstitution from a prior haploidentical BM transplant. For SCID-X1, the capacity to reinitiate thymopoiesis may be compromised in older patients with loss of thymic potential. Thus, gene therapy should be initiated as early as possible, and previous thymic activity may help predict success in older patients.

A combined 17 of the 20 enrolled SCID-X1 patients have been successfully treated in the French and UK studies. Unfortunately, the finding of leukemia in five patients, four from the French trial, and one from the United Kingdom trial, all of which were vector mediated, initially dampened enthusiasm for retroviral gene therapy. One patient died as a result of the leukemia, but the other four patients responded to treatment and retained gene-modified naïve T cells after leukemic therapy. However, the morbidity and mortality of this disease combined with the limitations of current transplantation protocols supported the continued use and refinement of this approach. The major focus of these continued efforts was on improved vector systems designed to reduce the potential for malignancy from vector-mediated insertional mutagenesis (discussed later). Preclinical data from these studies indicates additional studies of new vector types are forthcoming [67,130,131].

ADA deficiency

In ADA-SCID, an accumulation of deoxyadenosine triphosphate induces cell death by apoptosis in lymphocyte precursors, impairing lymphocyte development and function. ADA-SCID was one of the first diseases proposed for clinical trials because the gene was available and could be expressed from a retroviral vector, the level of protein required for therapeutic effect was estimated at 10–15% of normal levels, and corrected T cells would have a selective advantage. T cells were used initially as targets for the first clinical study of gene transfer to ADA-deficient patients in 1990 [132], and Aiuti et al. observed that, following transplantation of lymphocytes in one patient, discontinuation of polyethylene glycol (PEG)-ADA enzyme replacement therapy led to immune reconstitution [133]. Thus for ADA, the enzyme replacement therapy (ERT) likely reduces the survival advantage provided to gene-modified cells, limiting the potential therapeutic effect from ADA gene transfer.

Aiuti et al. treated two patients using CD34$^+$ BM cells transduced with a gammaretroviral vector and observed sustained engraftment and clinical improvement with restoration of ADA activity in peripheral blood lymphocytes [119]. Unlike previous studies, these ADA patients received non-myeloablative pretransplant conditioning with busulfan (2 mg/kg/day on days 3 and 2 before infusion), and did not receive PEG-ADA enzyme replacement therapy. Within the lymphocyte subsets, increased cell numbers were first detected in B cells and NK cells, followed by T cells. Both patients had corrected cells in multiple lineages including granulocytes, erythrocytes, megakaryocytes, and lymphoid cells. The frequency of gene-modified cells in the lymphoid subsets was higher, suggesting a stronger selective advantage for these cells. Virtually all NK cells in the peripheral blood and BM were transduced. In B lymphocytes, the frequency of transduced B cells was higher in the peripheral blood than in the BM, suggesting a growth or differentiation advantage for corrected peripheral B lymphocytes.

These investigators have now treated at least 30 patients without any evidence of leukemia. Integration site analyses on most of these patients have been published [134,135] and revealed polyclonality with chromatin structure and local histone modifications guiding vector insertion. These results were also compared with insertion sites identified in peripheral blood lymphocytes transduced with the same vector and transplanted into ADA-SCID patients, revealing cell-type specific differences in integration profiles consistent with transcriptional profiles of the individual cell types [135]. Gaspar et al. [136,137] treated six patients with no HLA-matched donor who had a poor response to PEG-ADA replacement therapy using a gammaretroviral vector pseudotyped with the GALV envelope. PEG-ADA was stopped 1 month prior to treatment, and autologous BM CD34$^+$ cells were transduced and infused in five patients after conditioning with melphalan at 140 mg/m^2. The sixth patient received 4 mg/kg busulfan conditioning prior to gene-modified cell infusion. Following gene therapy, T-cell counts rose in four of six patients and were sustained now more than 5 years since gene therapy. The other two patients restarted ERT and remain well. A third study conducted in the United States included 10 ADA-SCID patients and compared two different gammaretrovirus vectors, both based on the myeloproliferative sarcoma virus (MPSV), with one vector using the MPSV LTR and the other using the MPSV-modified MND LTR [123]. The first four patients treated in this study received no conditioning prior to infusion of gene-modified cells and remained on ERT during the transplant procedure. Two of these patients were older (15 and 20 years), while the other two patients were children (4 and 6 years). Only transient low-level gene marking was observed in the older patients, while some gene marking was sustained in the younger patients up to 9 years after gene therapy. However, this sustained marking was also lowlevel, though not as low as observed in the adult patients. This study went on to treat the remaining six patients with ERT withdrawal and busulfan conditioning (65–90 mg/m^2) prior to gene therapy. Three of these patients displayed complete immune reconstitution and remain off ERT up to 5 years after gene therapy. In those patients with sustained gene marking >1%, integration site analysis revealed polyclonal hematopoietic reconstitution with low-level diversity. Although clones displaying common insertion sites including *MDS1/EVI1* and *LMO2* were identified, there were no clinical consequences or noticeable expansion of these clones reported. Of all ADA-SCID patients treated to date, at least 19 patients have not required ERT after gene therapy. The difference in complete immunodeficiency correction compared to X-SCID is thought to be related to extrahematopoietic consequences of this disease and further studies in older patients and patients with diverse pretreatment histories have demonstrated that kinetics of naïve T-cell production were more rapid in younger patients and patients whose prior therapy did not include failed haploidentical BMT or ERT [123] (and reviewed in [138]). These studies support gene therapy for ADA-SCID as a viable approach for patients lacking an HLA-identical BMT donor and suggest intervention as early as possible after diagnosis and determination that a suitable donor does not exist. They also emphasize the need for preparative conditioning prior to gene-modified cell infusion in order to achieve therapeutic levels of engraftment.

X-linked chronic granulomatous disease

Chronic granulomatous disease is caused by a defect in the nicotinamide dinucleotide phosphate phagocyte oxidase (phox) complex, and approximately 70% of patients have mutations in the X chromosome gene encoding the gp91^{phox} subunit (X-linked chronic granulomatous disease). As a result, the antimicrobial activity of phagocytes is impaired due to an inability to generate reactive oxygen species, and patients have recurrent infections with granulomatous lesions. Unlike SCID-X1 or ADA-SCID, gene transfer to myeloid cells is required and the transgene does not confer a growth advantage to gene-modified cells, so high levels of gene transfer are likely necessary to observe a therapeutic effect. Supporting this, early attempts at gene therapy for chronic granulomatous disease in the absence of conditioning resulted in low levels of gene transfer without therapeutic benefit [139].

Ott et al. treated two patients after non-myeloablative conditioning with liposomal busulfan at 4mg/kg/day on days 3 and 2 before infusion [140]. In this study, G-CSF-mobilized CD34$^+$ were transduced with a gammaretroviral vector pseudotyped with the GALV envelope. In both patients, high levels of gene marking were observed and gene marking in peripheral blood leukocytes from patients 1 and 2 increased to 46% and 53%, and then decreased to 27% and 30%, respectively. Biochemical evidence of respiratory burst activity was demonstrated, and although the level of superoxide production observed was lower than in wild-type cells, clinical benefit was established for both patients. Analysis of vector integration sites initially showed a highly polyclonal repopulation, but after 3 months, clones with insertions in the *MDS*1-*EVI*1, *PRDM*16, and *SETBP*1 loci began to dominate. Transactivation of these genes by the strong spleen focus-forming virus promoter in the vector was found to have contributed to clonal expansion. The initial clinical benefit observed in these patients was attributed to this expansion; however, activation of the MDS-EVI1 locus led to genomic instability, monosomy 7, and development of myelodysplasia in both patients [15]. Both patients then demonstrated silencing of the therapeutic transgene by methylation of the viral promoter following the initial resolution of bacterial and fungal infections after gene therapy. One patient died of a severe bacterial sepsis after colon perforation. There was still very high gene marking in this patient, but the function of the transduced cells was greatly decreased. The second patient underwent allogeneic bone marrow transplantation from an unrelated, HLA-matched donor. Due to the use of busulfan prior to infusion of gene-modified cells, for allogeneic BMT a conditioning regimen of fludarabine, melphalan, and antithymocyte globulin (ATG) was used. This patient recovered rapidly following transplant and by day 115 after allogeneic BMT demonstrated 99.5% donor chimerism with almost complete elimination of MDS1/EVI1 clones harboring monosomy 7. A third patient suffering from therapy refractory *Aspergillus nidulans* infection of the lungs was treated with the same vector and protocol by another group after 8.8 mg/kg liposomal busulfan conditioning, resulting in stable gene marking at 20% up to 86 days after gene therapy was administered [141]. However, this patient also developed clonal myeloproliferation (reviewed in [142]).

In a third study conducted at the National Institutes of Health, three patients with incurable infection were treated with 10 mg/kg busulfan prior to infusion of CD34$^+$ cells gene-modified with an MFGS-based gammaretrovirus encoding gp91^{phox} as a salvage therapy [143]. One of these patients had been treated with gene therapy in an earlier study by the same group without conditioning prior to gene therapy approximately 11 years earlier. Despite initially high transduction efficiencies (25–73%) and large cell doses received at the time of cell infusion (18.9–71.0 × 10^6 cells/kg body weight), gene-modified cell levels in peripheral blood declined to 1% and 0.03% in two of the three patients and could not be detected after 4 weeks in the third patient. For the first patient, in whom 1% gene marking remained stable in peripheral blood up to 34 months after gene therapy, clone tracking between different lineages indicated that at least a few HSCs were transduced. A more recent report on this study indicated that the two patients who had detectable though declining gene marking at the time of the first report cleared their initial infections and have sustained gene marking at more than 5 years since gene therapy, albeit at very low levels (0.7–0.03%) [144]. Separately, a study conducted in Seoul, Korea infused two patients with $CD34^+$ cells transduced with a murine leukemia virus-based MT-$gp190^{phox}$ encoding gammaretrovirus after conditioning consisting of 6.4 mg/kg busulfan and 120 mg/m^2 fludarabine [145]. In this study, transduction efficiencies were reported to be 10.5% and 28.5%, respectively; superoxide-producing cells were, again, transiently detectable shortly after gene therapy, declining to 0.1 and 0.4%, respectively, in these two patients. Similarly, a clinical trial in London transplanted four patients with gene-modified cells; three patients with the same gammarertovirus used in the CGD trial where patients developed myelodysplasia and one patient whose cells were transduced with the gammaretrovirus used in the NIH trial (reviewed in [142]). In this study, all four patients received single-agent melphalan at a dose of 140 mg/m^2 prior to infusion of gene-modified cells. Similar transduction efficiencies were reported and cell doses ranged between 0.2 and 10 × 10^6 cells/ kg body weight. Again, low levels of gene marking were observed one month after transplant and declined to undetectable levels by day 42 after gene therapy.

The combined data from these studies, wherein only three patients displaying therapeutic benefit obtained such as the result of insertional mutagenesis and clonal expansion, suggest engraftment as the most significant barrier to successful CGD gene therapy. Additionally, similar gammaretroviruses have been used successfully in other gene therapy applications with similar levels of myelosuppression, substantiating the lack of *in vivo* selective advantage for transplanted CGD cells. In these trials, gammaretroviruses were used for gene transfer and it is possible that extended culture periods required for efficient gammaretroviral transduction may have compromised the multipotency of gene-modified $CD34^+$ cells. It has also been suggested that both HSCs and the niche in which they reside are damaged in CGD patients as a result of constant inflammation [142]. Furthermore, constitutive $gp190^{phox}$ expression in HSCs has been postulated to result in high levels of reactive oxygen species, resulting in cytotoxicity in this cell type. Additional trials utilizing lentivirus vectors to reduce *ex vivo* manipulation in combination with additional conditioning regimens and mature myeloid cell-directed $gp190^{phox}$ expression are planned.

Wiskott–Aldrich syndrome

Wiskott–Aldrich syndrome (WAS) is a recessive primary immunodeficiency with X-chromosome linkage which manifests in recurrent infections, thrombocytopenia, eczema, and autoimmunity. The WAS protein (WASP), which lacks functionality in this patient population, regulates actin polymerization in hematopoietic cells, serving to facilitate cell signaling and locomotion and to form immunologic synapses (reviewed in [146]). Thus, mutations in the *WAS* gene produce a complex biologic manifestation including defective T- and B-cell function, impaired function of the NK-cell immunologic synapse and compromised migratory capability in all white blood cells. Since WASP expression is restricted to hematopoietic cells, gene-modified leukocytes supplying a functional *WAS* gene would have an *in vivo* selective advantage over non-modified cells. Boztug *et al.* initially reported treatment of two WAS patients with mobilized autologous HSCs gene-modified with a GALV-pseudotyped gammaretrovirus expressing a functional *WAS* gene [147]. Three and two days prior to cell infusion, patients were conditioned with 4 mg/kg busulfan. In both patients, high levels of gene-marked, *WAS*-expressing leukocytes were observed, with skewing toward the lymphoid lineage. Functional correction restored NK immune synapse formation, increased T-cell receptor (TCR) usage in T cells and B-cell numbers in these patients. Clinically, both patients demonstrated platelet increases with cessation of clinical bleeding within 6–9 months after gene therapy. Incidence and severity of infections declined in both patients, although one patient experienced pneumococcal meningitis 2 years after gene therapy, hypothesized to be due to a prior splenectomy or insufficient B-cell reconstitution. Both patients also displayed decreased symptoms of autoimmunity. Initial gene-modified cell engraftment was observed to be polyclonal with some skewing towards common integration sites reported in other clinical trials of gene therapy employing gammaretrovirus vectors for gene transfer.

The trial continued to enroll and treat an additional eight patients; however, in 2009 it was reported that one patient had developed a clonal T-cell leukemia with retrovirus insertion proximal to the LMO2 locus, the same genetic locus identified in four out of five leukemic clones observed in the aforementioned X-SCID trial, which also utilized a gammaretrovirus vector for gene delivery [148]. Since that time, at least one additional patient has developed a T-cell leukemia, also with an oligoclonal expansion correlated with an *LMO2*-proximal retrovirus integration event [149]. This suggests that the combination of *in vivo* selective advantage mediated by therapeutic gene expression in combination with proto-oncogene proximal insertion of gammaretrovirus constructs resulting in local gene expression augmentation, specifically the *LMO2* gene, greatly increases the propensity for leukemic transformation in patients treated with gene therapy.

A second, internationally collaborative trial of WAS gene therapy wherein a SIN lentivirus is used to deliver the WAS gene under the control of the WAS promoter is currently underway and to date has treated a total of three patients [52]. Currently, there is no evidence of clonal expansion or leukemia reported in this trial and the therapeutic benefit of lentivirus-transferred WAS gene expression appears to be phenotypically corrective [150].

β-Thalassemia

Hemoglobinopathies of the β subtype are the most prevalent inherited single gene genetic disorders, resulting from mutations in the β-globin gene cluster and manifesting in little to no adult hemoglobin A production. Phenotypic symptoms include poor erythroid precursor maturation and, in Cooley anemia (significantly reduced or absent β-globin production), severe anemia requiring transfusion dependence which can result in iron overload, the leading cause of death in β-thalassemia patients. If an unaffected, matched sibling donor is available, and the patient is well transfused and chelated with good organ function, bone marrow transplantation can be curative, but this clinical scenario does not apply to the majority of β-thalassemia patients, making autologous gene therapy a viable clinical treatment option. However, for high-level, erythroid-specific expression required to be therapeutic, a complex transgene cassette that includes the β-globin gene and its introns, as well as the β-locus control region, must be transferred efficiently. The initial clinical trial employed a lentivirus construct to deliver the required genetic elements and reported treatment of two patients, one who failed to engraft due to technical compromise of the infused gene-modified cells independent of the gene transfer vector, and a second who engrafted with gene-modified cells after conditioning with busulfan (3.2 mg/kg/day for 4 days) [151]. This patient required a total of 10 additional transfusions over the first year after gene therapy, but with a noticeable decrease in frequency over months 6–12 (three transfusions compared to seven transfusions required in months 1–5). After 1 year, the patient became transfusion independent; however, this welcomed clinical benefit was found to be correlated with oligoclonal expansion of a gene-modified cell with a provirus integration in the third intron of the high mobility group AT-hook 2 (*HMGA2*) gene. *HMGA2* expression was increased dramatically in erythroid cells of this patient, but stabilized over time. The bone marrow of this patient did not indicate clinical symptoms of leukemic transformation, with only erythroid hyperplasia commonly observed in β-thalassemia patients noted. This was the first report of insertional gene activation coupled with oligoclonal expansion in lentivirus-transduced HSCs. At present, occurrences of HMGA2-associated vector insertion, without leukemic transformation, have been reported in multiple patients treated with HSC gene therapy for a variety of clinical conditions [104,152].

Fanconi anemia

Despite being an early candidate for HSC gene therapy, like chronic granulomatous disease, Fanconi anemia (FA) represents one of the more challenging monogenic diseases in which to accomplish successful therapeutic benefit from gene therapy. FA is an autosomal recessive disease resulting from mutations that compromise function in any one of 15 different genes, whose products work in concert to coordinate recognition and repair of damaged DNA. The clinical manifestation of FA, first described by Swiss pediatrician Guido Fanconi, is complex and can include congenital defects, short stature, abnormalities of the skin and arms, head, eyes, kidneys, and ears, as well as developmental disabilities. Almost uniformly, 90% of FA patients develop bone marrow failure by age 40. FA patients also display a significantly increased risk for acute myelogenous leukemia and other cancers including epithelial and squamous cell carcinomas [153]. As a result of the defect in DNA repair, FA patients are highly susceptible to DNA damaging agents, such as ionizing radiation and chemotherapy which induces DNA damage for cytotoxic effect, making even traditional bone marrow transplantation challenging. However, the largest barriers to successful HSC gene therapy identified to date have been the lack of HSCs available for gene modification and the fragility of these HSCs when manipulated *ex vivo* [116,154]. In two clinical trials attempted, one to treat FA patients of the C complementation group (*FANCC* gene mutation) [116] and the other to treat patients of the A complementation group (*FANCA* gene mutation) [154], both of which utilized gammaretroviruses for respective *FANCC* and *FANCA* gene transfer, a total of eight patients were infused with gene-modified cells. No conditioning therapy was utilized prior to infusion of gene-modified cells in either trial given the increased susceptibility of FA patients to DNA damaging agents. Both studies demonstrated transient engraftment only in some of the infused patients and, consequently, only temporary clinical benefit in those patients with transient engraftment.

Further preclinical studies have advocated the use of lentivirus vectors to mitigate gene transfer, as these vectors permit shorter *ex vivo* manipulation periods which are postulated to improve survival and engraftment potential of the limited number of HSCs available from FA patients [155,156]. In addition, multiple groups have shown a clear benefit to HSC preservation during *ex vivo* manipulation by addition of antioxidants to culture medium, as well as culture under hypoxic conditions, as this decreases the amount of oxidative stress placed on HSCs *ex vivo* [157,158]. In 2010, an international working group was established to determine the best strategy for HSC gene therapy in FA patients and reported that next steps should include a safety-modified lentivirus directing FA gene expression from a human phosphoglycerate kinase promoter and that minimal *ex vivo* culture with reduced oxidative stress should be attempted [159]. Currently a phase 1 clinical trial is enrolling FA patients to evaluate the feasibility and safety of the recommended approach [158]. However, the lack of engraftment or a proliferative advantage *in vivo* in the prior trials, as well as results from other HSC gene therapy trials such as those for ADA-SCID, X-CGD, and β-thalassemia, suggest that some preparative regimen may be required prior to gene-modified HSC infusion in order to achieve efficient and therapeutically beneficial engraftment in FA patients. Alternatively, *in vivo* selection after transplantation may also improve engraftment and proliferation by eliminating non-modified cells. It has been demonstrated that the sensitivity of FA cells to agents such as cyclophosphamide could provide a means for efficient engraftment and/or *in vivo* selection at very low doses of this drug [160].

Lysosomal storage disorders

X-linked adrenoleukodystrophy

X-linked adrenoleukodystrophy (X-ALD) is a severe genetic disease caused by mutations in the *ABCD1* gene, whose protein product, the ALD transporter, metabolizes very-long-chain fatty acids in the peroxisomal membrane. Loss of functional ALD transporter causes very-long-chain fatty acid accumulation in plasma and tissues as well as progressive demyelination within the central nervous system of ALD males. Sixty-five percent of these patients have an overall lifetime risk of developing fatal cerebral demyelination [161]. Allogeneic BMT, performed at early stages of demyelination, is the only treatment that has been shown to stabilize cerebral demyelination in ALD males. The mechanism for this stabilization arises from replacement of host brain microglial cells with that of donor myelomonocytic cells, although the exact mechanism by which this replacement arrests demyelination is unknown [162,163]. However, since the ALD transporter is not secreted, no cross-correction occurs in patients treated with allogeneic BMT. Furthermore, suitable donors are not available for all patients and for those whom donors are identified, risk for complications associated with allogeneic transplantation, including graft-versus-host disease (GVHD), remain a concern.

Preclinical studies of lentivirus-mediated *ABCD1* gene transfer into mouse ALD1-deficient hematopoietic stem/progenitor cells demonstrated replacement of 20–25% of brain microglia at 1 year after gene therapy [164]. Gene modification of $CD34^+$ cells from ALD patients also resulted in effective ALD transporter expression and these cells migrated to the brain in NOD/SCID mice after transplant, where they differentiated into microglia [165]. The initial clinical study employed a VSV-G pseudotyped HIV-1-derived SIN lentivirus vector expressing the *ABCD1* gene constitutively from a myeloproliferative sarcoma virus enhancer, negative control region deleted, dl587rev primer binding site substituted (MND) promoter [166]. Two patients were infused with G-CSF-mobilized CD34$^+$ cells transduced with this virus vector at an MOI of 25 after myeloablative conditioning with cyclophosphamide and busulfan due to the lack of a perceived selective advantage for gene-modified cells *in vivo*. Neither patient had an identified HLA-matched bone marrow or cord blood donor available. Hematopoietic recovery occurred within 2 weeks of transplant and immunologic recovery occurred within 1 year. Both patients' genetic mutation resulted in undetectable ALD transporter expression in peripheral blood cells, thus expression of transgenic *ABCD1* was used as a means of determining levels of gene-modified cells in circulation. Approximately 22–30% of peripheral blood cells expressed ALD transporter in the two patients at 2 months after gene therapy with copy numbers <1 per cell on average. Integration site analysis revealed polyclonal reconstitution with no evidence for dominant clones and identification of identical integration sites amongst purified cell populations of different lineages, suggesting true HSC gene modification had been achieved but at a very low level. Importantly, in both patients, arresting of cerebral demyelination occurred by 12–16 months after transplant and remained stable by MRI up to the latest follow-up (36 months). While this approach has been considered a breakthrough in treatment for X-ALD, additional studies aimed at enhancing the number of transduced HSCs, and thus shortening the time to demyelination arrest after transplant, are currently underway. While these initial results demonstrate the utility of lentivirus-mediated gene transfer to achieve therapeutic gene expression with safety (i.e., lack of insertional mutagenesis), additional follow-up is required to fully evaluate the long-term benefits and risks. However, another important feature of this research is the successful engraftment of gene-modified cells without an *in vivo* selective advantage after myeloablative conditioning, highlighting the importance of preparative regimens to achieve therapeutically beneficial hematopoiesis in gene therapy.

Metachromatic leukodystrophy

Metachromatic leukodystrophy(MLD) is an autosomal recessive genetic disorder resulting from mutations in either the arylsulfatase A (*ARSA*) gene or its activator protein, saposin-B (reviewed in [167]). Mutations in these genes result in variable ARSA expression and the accumulation of galatosyl and lactosyl sulfatides, manifesting in accumulation of these molecules in metachromatic granules of oligodendrocytes as well as many other cell types. Clinical symptoms vary with age of onset and affect both the central and peripheral nervous systems. As symptom onset can occur at any time during life and varies with stage of onset, MLD is divided into four onset categories: late infantile, early juvenile, late juvenile, and adult. Late infantile MLD and early juvenile MLD are the most commonly diagnosed stages, and all forms are considered terminal, with only supportive care currently available for patients. Recently, enzyme replacement therapy has entered early-phase clinical trials; however, blood–brain-barrier penetration has been a significant obstacle and efficacy data are pending (reviewed in [167]). There is conflicting evidence that bone marrow transplantation from unaffected donors results in significant therapeutic benefit, and this is thought to be due to the slow replacement of brain microglia and macrophage/histiocytes in the context of the rapidly progressive disease. Furthermore, the risks associated with allogeneic BMT still apply and not every patient has an available HLA-matched donor.

Preclinical studies of gene therapy using lentivirus vectors to deliver the ARSA gene under the control of a constitutive human phosphoglycerate kinase promoter resulted in significant therapeutic benefit in MLD mice, even more so than unaffected, non-gene-modified bone marrow, with reversal of neurologic deficits [168,169]. A phase 1 clinical trial to treat MLD patients was recently opened and initial reports of efficacy and safety are pending [52]. Preliminary reports have indicated that, like the ALD trial, patients were treated with fully myeloablative chemotherapy (busulfan) prior to infusion of gene-modified cells, and that marking in the first 6 months after gene therapy has remained stable [17].

Solid tumors

Glioblastoma multiforme

Glioblastoma multiforme (GBM) is a nearly uniformly fatal brain tumor for which decades of clinical research has provided little therapeutic options. Patients who are not eligible for surgical intervention who choose palliative care only survive a median of 3 months from diagnosis. The most effective therapy includes surgery to remove as much of the primary mass as possible, followed by cranial-focused radiation therapy with concomitant administration of temozolomide, an alkylating agent chemotherapy, followed by adjuvant cycles of temozolomide. However, this intense treatment strategy adds less than 2 years median survival to GBM patients (21 months). Additionally, for approximately 60% of GBM patients, epigenetic changes in tumor cells result in increased expression of endogenous methylguanine methyltransferase (MGMT), a protein which repairs cytotoxic DNA damage caused by temozolomide, rendering tumor cells resistant to standard therapy [170]. A small molecule, O6-benzylguanine, can irreversibly inactivate MGMT and is postulated to restore temozolomide sensitivity in GBM cells; however, early phase trials to assess the efficacy of this therapeutic strategy resulted in severe hematopoietic toxicity [171,172]. An earlier study had reported that MGMT expression is epigenetically silenced in most blood cells and is undetectable in HSCs, making them particularly sensitive to the combination of O6-benzylguanine and temozolomide [173]. Interestingly, toxicity of this regimen was not observed outside of the hematopoietic compartment. Thus, it was envisioned that gene therapy could provide MGMT expression within the marrow to protect the hematopoietic compartment from chemotherapy-induced toxicity, while brain tumor cells remained sensitive. As described earlier, chemotherapy-resistance genes, such as mutant *MGMT*, which confers resistance to alkylating agent chemotherapy, are a promising approach for mediating *in vivo* selection of gene-modified cells in patient populations where selective advantage is not conferred by gene modification. Specific for mutant *MGMT* is the ability to maintain DNA repair capacity while being insensitive to the inhibitory effects of O6-benzylguanine.

The first trial of HSC gene therapy with mutant MGMT was conducted in adult GBM patients who displayed the poor prognosis phenotype of unmethylated (expressed) MGMT in tumor cells [104]. Following surgical intervention and standard radiation without concomitant temozolomide, three patients were treated with single agent BCNU at a dose of 600 mg/m^2 as both a conditioning agent and as chemotherapy, since this agent is known to cross the blood–brain barrier and is active against GBM cells. Two days after BCNU administration, patients received G-CSF-mobilized CD34$^+$ cells transduced with a GALV-pseudotyped gammaretrovirus expressing the mutant MGMT P140K from the endogenous viral LTR promoter. Within 1 month after transplant, gene marking levels were between 35 and 60% of circulating white blood cells (Figure 8.5),

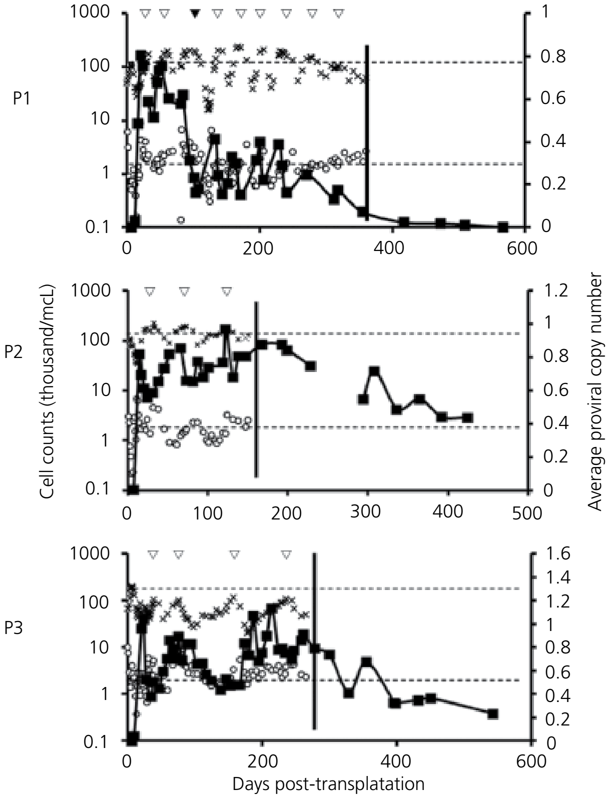

Figure 8.5 Persistance and chemoprotection of P140K gene-modified cells in three glioblastoma patients. Primary *y*-axis represents ANC, lymphocyte, and PLT counts in PB as a function of time and chemotherapy.Cell counts are in thousand per cubic millimeter (mm^3) and are shown for various time points after transplantation of gene-modified cells (*x*-axis). Crosses (x) represent PLTs and open circles (o) represent ANC. Dashed lines (--) represent retreatment threshold of PLTs (upper dashed line) and ANC (lower dashed line). Secondary *y*-axis represents average proviral copy number per genome as determined by real-time PCR at various time points post-transplantation (*x*-axis) in bulk WBCs (closed squares; ■). Inverted open triangles (▽) indicate cycles of O6BG/TMZ chemotherapy. Closed triangle (▼) in P1 graph represents single dose-escalated cycle of TMZ (590 mg/m^2). Source: Adair et al. 2012 [104]. Reproduced with permission from the American Association for the Advancement of Science.

and patients began receiving combination chemotherapy including O6-benzylguanine and temozolomide at a dose of temozolomide that was reported to be the maximum tolerated dose from the previous trials, which did not include gene therapy (472 mg/m^2). All three patients were able to receive more chemotherapy cycles than the average reported for patients in the prior trial without gene therapy, and all survived beyond the expected mean with one patient alive and apparently disease-free after nine chemotherapy cycles. Clonal analysis in these patients did reveal emergence of three dominant clones, two in the same patient, after two or three chemotherapy cycles, including integrations in proximity to the PR-domain-containing 16 (*PRDM16*) and *HMGA2* genes. However, this clonal skewing within the gene-modified cell pool occurred without continued expansion in the white blood cell compartment or evidence for MDS or leukemia in bone marrow or peripheral blood. The report also noted an enrichment for clones harboring provirus insertions in common genomic loci over time and chemotherapy, and these loci overlapped with those reported in other clinical trials using gammaretrovirus vectors for gene transfer. Importantly, none of the patients displayed extrahematopoietic toxicity during the study, underscoring the potential for this strategy in the treatment of cancer. Despite the lack of leukemic transformation in these patients, use of a lentivirus vector to mediate gene transfer is thought to be a safer alternative to avoid insertional mutagenesis and potential for transformation and may be used in future studies.

Infectious disease

HIV

While the development of highly active antiretroviral therapy (HAART) has greatly improved the outcome for HIV$^+$ patients, it is not curative, represents a large expense for patients, and carries associated risks for both therapy-related side effects and virus evolution. Recently, proof-of-principal evidence that transplantation of HSCs could result in a functional HIV cure resulted when an HIV$^+$ leukemia patient was transplanted with allogeneic bone marrow from a donor who carried a mutation in the C-C chemokine receptor type 5 (CCR5) gene following myeloablative chemotherapy and resulting in apparent elimination of detectable HIV in the recipient in the absence of HAART [53]. However, widespread use of this strategy is limited by the percent of mutant CCR5 carriers and the combined difficulty in identifying an HLA-matched bone marrow donor. As noted earlier, targeted gene disruption is one strategy currently being pursued as a means of generating autologous mutant CCR5 HSCs. Another strategy is to transfer genes whose products are capable of interfering with HIV infection to autologous HSCs. Transplantation of autologous HSCs in patients with high-risk or relapsed AIDS-related lymphoma (ARL) receiving myeloablative conditioning was shown to support long-term survival [174]. The same group first attempted gene therapy of HSCs in this population since these patients were already receiving autologous HSCs and myeloablative conditioning prior to cell therapy [175]. In this study, a total of seven patients with high-risk or relapsed ARL were consented to treatment, which included G-CSF (10 mcg/kg) for mobilization followed by leukapheresis to collect a total of 5×10^6 CD34$^+$ cells/ kg body weight. One half of these CD34$^+$ cells were cryopreserved as unmanipulated therapeutic product and the other half was subjected to lentivirus transduction with a VSV-G-pseudotyped vector encoding three HIV-counteracting transgenes. One gene product inhibited viral entry with a CCR5 ribozyme, a second inhibited viral RNA transport by RNA interference of the viral tat/rev element, and the third gene product inhibited initiation of viral transcription by expressing a decoy RNA. One patient displayed progressive disease preventing further treatment and a second patient failed to meet the established collection goal of 5×10^6 CD34$^+$ cells/kg. Of the five remaining patients, one patient was administered only unmanipulated cell product as the transduced cell product failed to meet release criteria (viability) prior to infusion. All five patients received myeloablative conditioning prior to cell infusion including BCNU, etoposide, and cyclophosphamide. The four patients who received gene-modified cell products also received unmanipulated cell products and all patients remained on HAART throughout the study. All patients engrafted by 11 days after transplant, as evidenced by absolute neutrophil count >500/μL for 3 consecutive days. *In vitro* assessment of transduction efficiency in 4-week culture-initiating cells isolated from transduced products was very low (0.11–0.15%). At the time of publication, 18 months of follow-up had been conducted and all patients were in remission from their lymphoma. Gene marking in these patients ranged from 0.02–0.32% of peripheral blood mononuclear cells. Viral load in these patients was undetectable, which is not surprising considering that HAART was maintained throughout the treatment period. One patient displayed an increased viral load of 890 gene copies per milliliter at 15 months after gene therapy, following HAART discontinuation between months 12 and 15. The patient resumed HAART after this test result and returned to undetectable viral load thereafter. It is postulated that both the co-infusion of unmanipulated cell products and continuity of HAART therapy may have contributed to the low-level gene marking observed in these patients.

Vector-mediated insertional mutagenesis

Leukemia in the SCID-X1, chronic granulomatous disease and Wiskott–Aldrich syndrome trials

The ability of retroviruses to efficiently integrate into the genome is also a disadvantage; retroviral vectors are insertional mutagens and can cause leukemias, as observed in the French SCID-X1, CGD, and WAS gene therapy trials. It has long been known that many gammaretroviruses (formerly oncoretroviruses) cause leukemia, but it was previously thought that replication-incompetent vectors had a low risk of insertional mutation leading to malignancy. Leukemias were not observed as a result of vector integration in previous clinical T-cell gene transfer experiments, possibly in part due to the biology of T cells [176]. Leukemias were also not observed in many HSC large-animal gene transfer experiments (reviewed in [61]). This is in contrast to replication-competent viruses, where multiple rounds of infection *in vivo* would greatly increase the risk for malignancy. Leukemia was observed in three of 10 rhesus macaques when replication-competent retrovirus contaminated a vector preparation used for gene transfer to enriched BM cells [177].

In all three trials in which myelodysplasia or leukemia developed, there was no evidence of replication-competent retrovirus, and studies were undertaken to characterize vector integration sites to understand the etiology of the transformed cells. In leukemic cells identified in both the X-SCID and WAS trials, vector integrants were observed near the *LMO2* and *CCND2* genes. The *LMO2* gene encodes a transcription factor involved in early hematopoiesis that had previously been involved in leukemogenesis via chromosomal translocation (reviewed in [178]). It is also unclear if the therapeutic transgene for γc was involved in the leukemias, possibly through aberrant IL receptor signaling. Expression of γc from a lentiviral vector was found to cause lymphoma in a mouse model [179], and a database of viral integrations from mouse tumors identified a leukemia with integrations at both the *IL2RG* and *LMO2* loci [180], suggesting that they could cooperate to contribute to leukemia. Overexpression of γc alone in human CD34$^+$ cells had no effect on T-cell development in vitro, and it has been suggested that integration at LMO2 may represent the primary oncogenic event and that restoring IL-7 signaling with the γc transgene creates a preleukemic condition of immature cells under intense proliferative pressure [181]. However, the development of leukemia with insertions proximal to *LMO2* in the WAS gene therapy trial demonstrated that insertional mutagenesis and genotoxicity of HSC gene therapy with gammaretrovirus vectors extends beyond X-SCID to other diseases. This data suggested that specific diseases, especially those where the therapeutic transgene confers an inherent selective advantage to gene-modified cells, may have inherent risks from a perspective of vector-mediated insertional mutagenesis, and that preclinical models may yield insights into the potential adverse side-effects of proposed clinical trials. However, the report of myelodysplasia as the result of retrovirus integration and insertional activation of the *MDS/EVI1* gene in patients with chronic granulomatous disease treated with gene therapy suggests that selective advantage of the therapeutic transgene may not be the only factor contributing to leukemogenesis. More confounding is the occurrence of expanded clones with or without proximal gene activation, which remain stably elevated for years without evidence for leukemic transformation, such as the *PRDM16* and *HMGA2* clones observed in the gene therapy trials including β-thalassemia and GBM patients. These observations support the growing mass of evidence suggesting that multiple genetic and epigenetic events are required to transform normal cells into tumor cells (reviewed in [17]).

Deregulation of host genes by vector proviruses

An area of active investigation towards safer HSC gene therapy is the development and testing of vectors with an improved safety profile. Gammaretroviral vectors have a preference to integrate close to the promoters of genes [182], lentiviral vectors have a preference to integrate within highly expressed transcripts [183], and foamy virus vectors integrate less frequently near promoters than gammaretroviral vectors and less frequently than both gammaretroviral and lentiviral vectors within transcripts [184]. Although the mechanisms of these integration preferences are not yet well understood, they appear to be defined in part by tethering interactions between the pre-integration complex and host proteins, and also by the state of host chromatin (reviewed in [185]). Integration by retroviral vectors can deregulate host genes by several mechanisms (Figure 8.6), with the potential to lead to clonal dominance, as observed in the CGD trial, and to leukemia as observed in the

Figure 8.6 Deregulation of cellular genes by integrated vector proviruses. There are several mechanisms whereby integrated vector proviruses can deregulate the gene expression of proto-oncogenes, tumor suppressors, or genes involved in hematopoiesis. Four examples of deregulation are illustrated. The integrated vector provirus is indicated by two long-terminal repeats (LTRs) with an internal transgene indicated by a hatched box. The cellular gene promoter and exons are indicated by a black box and gray boxes, respectively. In (a), transcription initiated from the vector 3′ LTR transcribes the cellular gene at increased levels. In (b), enhancers in the vector LTRs activate transcription from the cellular promoter increasing transcription. In (c), transcription from the vector 5′ LTR results in a spliced mRNA that creates a novel truncated isoform of the cellular gene that may have distinct properties from the native form, including oncogenicity. In (d), the vector provirus is integrated between the second and third exons, thereby disrupting transcription of the cellular gene via premature polyadenylation using the 3′ LTR polyadenylation signal.

French SCID-X1 trial. Gammaretroviral vector integrants can deregulate the expression of genes over 500 kb from the insertion site [186], and a comparison of the frequency of integrants in canine repopulating cells shows that a significant percentage of gammaretroviral, lentiviral, and foamy virus vectors are observed near genes that have been associated with malignancy [187]. Thus, vector designs that reduce the ability of integrated vector proviruses to deregulate the expression of nearby genes should reduce the potential for malignancy.

Approaches to reduce the potential for vector-mediated malignancy

There are several modifications that can be made to improve vector safety, including using SIN vectors. Unlike the LTR-driven vectors used in the SCID-X1 trials, in SIN vectors the promoter–enhancer sequences are removed, greatly reducing the potential for transcriptional activation by the 3′ LTR and for enhancer activation by both LTRs. Inserting insulator sequences into the LTRs that interfere with enhancer activation of nearby genes has also been proposed as a safety feature, and experiments in a human T-cell line suggest that lentiviral vectors with a chicken HS4 insulator may have a reduced potential for clonal dominance [188]. In the reported gene therapy trial for β-thalassemia discussed earlier, a therapeutic β-globin-expressing lentiviral vector with a chicken HS4 insulator was used. Interestingly, in the dominant clone observed in this study, only one copy of the HS4 250 bp core element was present in this vector, despite the fact it was engineered to have two copies. The single 250 bp core region does not contain the full insulating capability of the 1.2 kb chicken HS4 insulator, which may have contributed to the inability of this vector modification to block clonal dominance. A straightforward approach to improve safety is to use lineage-specific promoters in the context of a SIN vector to restrict gene expression to the desired hematopoietic lineage. This should reduce the possibility of deregulating proto-oncogenes in stem cells and in lineages where gene expression is not required (reviewed in [189]).

Efforts to target the integration of retroviral vectors to defined locations by modifying components of the retroviral pre-integration complex have also been explored. Yeast LTR retrotransposons provide a compelling precedent for targeted integration into a eukaryotic genome. Yeast retrotransposons have many similarities to retroviruses yet have a remarkable specificity for integration. The Ty3 retrotransposon integrates in a small window, two or three nucleotides upstream of Pol III transcripts. To date, targeting the integration of retroviral vectors has been much less efficient. In one study, a zinc finger protein with a unique address was fused to the lentiviral Pol [190]. The integration profile was modified, but titers were greatly reduced, limiting the potential of this approach. Re-targeting of lentiviral vectors has been achieved using engineered target cells that express modified versions of the host protein lens epithelium-derived growth factor (LEDGF). LEDGF contains a domain that binds the HIV integrase and interacts with the HIV pre-integration complex, thereby tethering the complex to sites where LEDGF binds. By modifying the binding specificity of LEDGF, HIV integration can be re-targeted [191–193]. This approach suggests that efficient re-targeting of retroviral vectors can be achieved. However, the challenge is now to devise an approach to efficiently re-target integration in normal CD34$^+$ cells that have not previously been modified with an altered LEDGF.

Another approach is to avoid integration by correcting HSC genes or introducing therapeutic genes at specific chromosomal locations using a gene targeting approach. The frequency of conventional gene targeting by transfection is low in human primary cells, but targeting frequencies can be greatly increased by cleaving the target site with a nuclease to stimulate homologous recombination. Modification of the γc locus was obtained in up to 18% of human hematopoietic cells using a zinc finger nuclease (ZFN) [194], and targeted gene addition using this approach is also remarkably efficient in hematopoietic cell lines [195]. Integrase-deficient lentiviral vectors have been developed for the efficient delivery of DNA donor templates and ZFNs to stem cells. Non-integrating lentiviral vectors that express ZFNs have led to targeting in up to 30% of cells in hematopoietic cell lines, with targeted gene addition in up to 5% of human hematopoietic progenitor cells [196].

Summary and future directions

Advances in the ability to enrich and transduce human repopulating cells have led to recent successes in HSC gene therapy. The unfortunate occurrence of leukemia in three clinical trials of gammaretrovirus-mediated HSC gene therapy has stimulated research into defining the relative safety of different gene transfer approaches and developing safer vectors. However, it also needs to be emphasized that for some diseases like SCID-ADA, even current vector technology appears to be safe and highly efficient. For diseases that have been associated with insertional mutagenesis, novel vector systems and gene targeting/editing approaches are being explored. A number of recently described nucleases including ZFNs, homing endonucleases (HEs), and Tal effector nucleases (TALENs) are currently in preclinical studies. The use of ZFNs to disrupt the CCR5 locus in T cells of HIV$^+$ patients is currently in clinical studies. Thus, over the next 5 years it can be expected that HSC gene therapy for most of the afore-mentioned diseases will shift to newer, safer vector systems like lentivirus vectors, foamy virus vectors, or alpha retrovirus vectors. For some diseases that can be treated with gene disruption, such as CCR5 disruption for generating cells resistant to HIV infection, we would also expect to see nuclease-mediated gene editing studies. These advances will likely translate to the cure of many genetic diseases affecting the hematopoietic system and extend to other diseases like HIV, where gene therapy can potentially restore immune function, as well as certain cancers where HSC gene therapy can improve chemotolerance of blood and marrow cells potentially resulting in more effective chemotherapy dosing and improved survival.

Introduction

Immunology plays a central role in allogeneic hematopoietic cell transplantation (HCT). Any appreciation of the immunologic mechanisms involved in engraftment, graft-versus-host disease (GVHD), control of malignancy, the development of tolerance, and immune reconstitution requires some understanding of the cellular and molecular components involved in immune reactions provoked by grafting tissue from one individual to another. Insight into the cellular basis of alloreactivity requires an understanding of immune recognition, the development of the immune system, and the nature of immune responses. This chapter will serve to introduce the reader to the immunology of HCT. Citations are made to selected reviews and reports from the recent literature and to other chapters that provide detailed information.

Fundamental differences between pathogen and transplantation responses

Since the immune system evolved as a defense against pathogens and not under the selective pressure of HCT, the key differences between antipathogen and alloimmune responses deserve consideration (Table 9.1) [1]. A working paradigm for antipathogen immunity holds that pathogens are first encountered by innate cells, including antigen-presenting cells (APCs). These cells detect the presence of pathogen-derived products through an array of sensing mechanisms that decode the nature of the pathogen and initiate the production of specific signals and mediators directed to the particular class of pathogen. These innate cells directly mediate antipathogen immunity and, in addition, they present pathogen-derived antigens to T lymphocytes (T cells), thereby initiating an adaptive immune response. The combined innate and adaptive responses work together to contain and clear the pathogen. In HCT, no known equivalent of a pathogen-derived product alerts either donor or recipient innate cells to the presence of alloantigen. Yet, the infused donor cells both provoke an immune response by recipient immune cells that survive conditioning regimens and generate a potent immune response against the recipient. Pathogens and alloantigens also differ in their persistence and locations. Pathogens typically are tropic only for subsets of cells, and only a fraction of APCs will therefore present pathogen-derived products. In HCT, every recipient cell is a source of alloantigen, every donor-derived APC has ready access to alloantigen, and the supply of recipient antigen is unlimited, akin to chronic infections. Likewise, for rejection responses, all donor cells and APCs are sources of alloantigen. Other relevant differences are worth considering. Mature donor T cells, the primary mediators of GVHD and graft-versus-leukemia effects (GVLEs), are infused and must find their way to sites where alloantigen is presented, whereas they are already present in secondary lymphoid organs at the time of pathogen exposure. Finally, most conditioning regimens and some therapies used to control malignant cells before HCT create a lymphopenic environment, which can have significant effects on T-cell activation and the development of effective responses.

Fundamental differences between hematopoietic cell transplantation and solid organ transplantation

HCT differs fundamentally from grafting of most other organs. In solid organ transplantation, the graft generally contains only limited numbers of cells with immunologic function. The primary clinical concern rests with preventing rejection by the recipient immune system. Lifelong administration of immunosuppressive medication is generally required in order to prevent rejection not only by cellular and humoral mechanisms in the recipient at the time of transplantation, but also by those generated from recipient-derived immunologic precursors after transplantation.

The preparative regimen administered before HCT (see Chapters 19–23) eliminates a variable number of precursors and mature cells of the recipient immune system, depending on the intensity of the regimen. The graft contains large numbers of precursors and mature cells that replace those of the recipient. Thus, the donor graft generates the immune system in the recipient. The primary clinical concerns rest not only with preventing graft rejection by recipient cells that survive the conditioning regimen, but also with preventing donor cells from causing immune-mediated injury (GVHD) in the recipient, while allowing immune reconstitution for recognition and control of pathogens. Immunosuppressive medications

(see Chapter 81) are administered after transplantation primarily to prevent GVHD. Eventually, it becomes possible to discontinue such treatment in most patients. The subsequent persistence of engraftment and the absence of GVHD, together with recovery of host immune defenses, indicate that a state of immunologic "tolerance" has been achieved between the donor and recipient, although the mechanisms that maintain this tolerance are not fully understood.

Transplantation antigens

Major histocompatibility antigens

Immune reactions provoked by grafting tissue from one individual to another are caused by transplantation or histocompatibility antigens (see Chapter 10). Genes encoding transplantation antigens are located both within and outside the major histocompatibility complex (MHC) [2]. The human MHC is located on the short arm of chromosome 6 and contains a series of genes encoding two distinct types of highly polymorphic cell surface glycoproteins termed human leukocyte antigens (HLAs). HLA class I antigens contain a single polymorphic α chain non-covalently associated with β_2-microglobulin. HLA class I antigens encoded by three loci termed HLA-A, HLA-B, and HLA-C are known to provoke immune reactions in HCT. The role of antigens encoded by other class I loci has not yet been defined. As of August 2012, 1448 HLA-A alleles, 1988 HLA-B alleles, and 1119 HLA-C alleles with protein-changing exon polymorphisms had been described (http://www.ebi.ac.uk/imgt/hla/stats.html).

HLA class II antigens are encoded by three clusters of loci (HLA-DR, -DQ, and -DP) and contain a single α chain non-covalently associated with a β chain. The α chains of the HLA-DR, -DQ, and -DP antigens are encoded by the respective *DRA*, *DQA1*, and *DPA1* genes, while the β chains are encoded by the respective *DRB*, *DQB1*, and *DPB1* genes. Nine distinct *DRB* genes encode polymorphic HLA-DR β chains. Antigens encoded by the *DRB1*, *-DQ*, and *-DP* genes are known to provoke reactions in HCT. The role of antigens encoded by other *DRB* genes has not yet been defined. As of August 2012, 2 HLA-DRA alleles, 860 HLA-DRB1 alleles, 29 DQA1 alleles, 126 DQB1 alleles, 17 DPA1 alleles and 134 DPB1 alleles with protein-changing exon polymorphisms had been described. Extensive polymorphism of HLA class I and class II molecules has evolved as a mechanism to protect both individuals and the population by increasing the range of pathogen-associated antigens that can be recognized by the immune system.

HLA matching

The genes encoding HLA class I and class II antigens are tightly linked, such that they are inherited in families as "haplotypes" with low recombination frequencies [2]. An HLA-matched sibling can be readily identified by an informative family study, especially if family members are HLA-heterozygous and if the parental haplotypes can be identified by reliable markers and clearly assigned by segregation analysis. A given patient has a 0.25 probability that any one sibling inherited the same paternal haplotype and the same maternal haplotype, thereby being "HLA-genotypically identical." Siblings identified in this way are identical not only for the polymorphisms detected by HLA typing, but also for all other polymorphisms in the MHC. The term "HLA-matched" has a different significance when applied to unrelated individuals. In this context, the assessment of matching is based on the relatively limited number of polymorphisms encompassed by the testing. Unrelated individuals who are HLA-phenotypically identical have considerable mismatching at MHC loci that are not assessed by the methods used for HLA typing. Because of the highly polymorphic nature of HLA antigens, the probability that two unrelated individuals have the same HLA-A, -B, -C, -DR, -DQ, and -DP alleles is extremely low.

HLA-haploidentical related pairs have a shared haplotype that is identical by descent for all polymorphisms in the MHC and two distinct non-shared haplotypes, one in the donor and the other in the recipient. Matching of the non-shared haplotypes is based on the relatively limited number of polymorphisms encompassed by the testing, except in cases where the non-shared haplotypes differ because of parental meiotic recombination. In these cases, a portion of the non-shared MHC haplotypes is identical by descent for all polymorphisms.

Structure of HLA and cell biology of antigen presentation

MHC class I and class II molecules bind short peptides for display at the cell surface, where they can be recognized by T cells (Figure 9.1) [3]. Each specific MHC molecule displays a characteristic preference for binding peptides with distinctive characteristics, and this preference in part is responsible for the MHC-restriction of T-cell responses. MHC class I and class II antigens have similar structures [2]. The general structure consists of a floor formed by eight antiparallel β strands overlaid by two α helices in antiparallel orientation to each other, leaving a groove or cleft between them for binding of small peptides. The polymorphic residues of HLA molecules are located predominantly in the β-strand floor and in positions on the α helices that point into the groove between the two helices, where they help to determine the repertoire of peptides that bind to a given HLA molecule.

Since MHC molecules present alloantigen to alloreactive T cells, it is important to understand how protein antigens are processed into peptides and how MHC molecules present these peptides. In nearly all nucleated cells, peptides that bind MHC class I molecules can be generated from endogenous proteins [3]. In a much smaller subset of cells, including some APCs, peptides that bind MHC class I molecules can be generated from endocytosed proteins, from proteins contained in endocytosed cells or cell fragments, or from proteins taken up by surface receptors [4]. This process is called "cross-presentation." Ubiquitin-modified proteins of endogenous or exogenous origin are degraded in the cytosol by proteasomes [5]. These protease enzymes exist as a constitutive form in all cells and as an induced "immunoproteasome" form in cells stimulated with interferons. The peptides produced by immunoproteasomes differ from those produced by constitutive proteasomes and could be particularly relevant in the context of transplantation. The resulting peptides are transferred into the lumen of the endoplasmic reticulum

Figure 9.1 Antigen presentation. Left side: MHC class I presentation. Peptides are generated in the cytosol by proteasome-mediated cleavage of endogenous intracellular proteins. Peptides are also delivered to the cytosol through endoplasmic reticulum-associated degradation (ERAD). Cytosolic peptides are channeled into the endoplasmic reticulum (ER) through the transporter associated with antigen presentation (TAP), loaded into MHC class I molecules and delivered to the cell surface through the Golgi apparatus for antigen presentation to CD8⁺ T cells. Right side: MHC class I cross-presentation. In the vacuolar pathway, material ingested by phagocytosis is degraded into peptides in the phagosome, and loaded into MHC class I molecules and delivered to the cell surface. In the cytosolic pathway, material ingested by phagocytosis is exported to the cytosol and digested into peptides by proteasomes. Peptides are then transported into either endoplasmic reticulum or phagosomes for loading into MHC class I molecules and delivery to the cell surface. Peptide transport into both compartments is mediated by TAP. Incorporation of TAP into phagosomes is mediated via transfer from the ER into the ER-Golgi intermediate compartment (ERGIC). The interaction of SEC22 with syntaxin 4 mediates the transfer of TAP from the ERGIC into phagosomes. Bottom: MHC class II presentation. Exogenous proteins ingested via phagocytosis, endocytosis, pinocytosis and uptake receptors are digested by proteases in early endosomes and in the MHC class II compartment (MIIC). MHC class II molecules are synthesized in the endoplasmic reticulum and complexed with the invariant chain (Ii). The complexes are transported directly or via surface endocytosis to the MIIC. In this compartment, Ii chains are cleaved by proteases, leaving the class II-associated Ii peptide (CLIP) in the groove between the α helices of MHC molecules. CLIP is replaced by internalized peptides through the influence of a molecular chaperone (HLA-DM in humans, H2-M in mice). Peptide-loaded MHC class II molecules are delivered to the cell surface for antigen presentation to CD4⁺ T cells. by an adenosine triphosphate-dependent transport mechanism. The transport mechanism functions most efficiently with peptides containing 8–12 amino acids with a hydrophobic residue at the carboxy terminus. Peptides bind MHC class I molecules in the endoplasmic reticulum.

Peptides that bind MHC class II molecules generally originate from extracellular proteins that are taken into cells by endocytosis and other mechanisms [3], although direct presentation of intracellular proteins also occurs. Acidification of endosomes activates proteases that degrade internalized proteins into peptides. Peptides bind MHC class II molecules when endosomes fuse with vesicles containing newly synthesized membrane proteins being transported to the cell surface. Binding of peptides to MHC class I and class II molecules is dictated by the way that the side chains of specific residues of the peptide fit into pockets formed by polymorphic residues lining the groove between the α helices of MHC molecules.

Minor histocompatibility antigens

Minor histocompatibility antigens (mHAs) are the MHC-binding peptide products of coding polymorphisms that distinguish recipients and donors [2,6], whereas major histocompatibility antigens originate from the polymorphisms of intact MHC molecules. mHAs can be generated by a variety of mechanisms, including gene insertions and deletions, differences between Y and X chromosome homologs, amino acid coding changes resulting from single nucleotide polymorphisms, allelic mRNA splice variants, and post-translational modifications of amino acids. Proteins that give rise to mHAs molecules must be processed into peptides for MHC presentation as described above. Recognition of an mHA by T cells is specified both by the polymorphic peptide and the MHC molecule to which it is bound and by the availability of T cells with receptors capable of binding the peptide–MHC combination. Polymorphisms producing a single amino acid substitution in a peptide presented by MHC molecules can be sufficient to generate a T-cell alloimmune response in the absence of any MHC disparity. Only a few mHAs have been defined biochemically. Genetic studies in mice have identified more than 40 loci that encode mHAs, each typically having two known alleles. Human genomes contain more than 15,000 protein-changing single-nucleotide polymorphisms. Because these polymorphisms are distributed throughout the entire genome, siblings other than identical twins always have considerable disparity for mHAs, even when they are HLA-matched, but the immune system responds to only a small number of "immunodominant" antigen mismatches between the donor and recipient.

Differences in responses against major and minor antigens

Immune responses against MHC antigens differ greatly from responses against mHAs [7]. The frequency of T cells that respond to any given MHC antigen has been estimated at 1–10%. For this reason, generation of an in vitro response against MHC antigens does not require in vivo priming. MHC antigens also induce alloimmune antibody responses detectable by serologic testing. The frequency of T cells that respond to any given mHA has been estimated at 0.01–0.10%. Generation of an optimal in vitro response against mHAs typically requires prior in vivo priming, but with repeated stimulation, expanded T-cell populations reactive against mHAs can be generated from naïve T cells [8]. Polymorphic peptides loaded into MHC molecules do not generate antibody responses, but donor B cell-derived antibodies can be generated against recipient-specific proteins [9].

At least two mechanisms might account for the higher precursor frequencies of T cells against major histocompatibility antigens compared with mHAs. First, a given major histocompatibility antigen binds a diverse set of peptides that can all be presented to T cells, and the collective set of peptide–MHC complexes elicits a response from multiple sets of T-cell clones, with each set specific for a different peptide–MHC complex. In contrast, mHAs are composed of a single peptide presented to T cells by a specific MHC molecule, and the complex elicits a response from a single set of T-cell clones, all specific for the same peptide–MHC complex. This framework is consistent with observations that the variety of epitopes and numbers of responding T cells are far greater for major histocompatibility antigens than for mHAs. A second hypothesis to account for the high precursor frequency of T cells reactive against non-self MHC proteins is that certain T-cell clones can recognize a specific MHC molecule in conjunction with a variety of peptides, whereas T-cell clones specific for mHAs recognize a single peptide in conjunction with a specific MHC molecule. According to this scenario, the T-cell receptor (TCR) binding energy is presumed to derive primarily from interactions with the MHC molecule as opposed to the peptide. The ability to recognize a major histocompatibility molecule in conjunction with a variety of peptides greatly increases the cell surface density of epitopes available for stimulation of a T-cell clone and perhaps permits TCRs with lower affinity to contribute to T-cell activation. Regardless of mechanism, the higher frequency of T cells capable of recognizing a major histocompatibility antigen versus an mHA has an important practical consequence: for any given number of donor T cells in the graft, GVHD caused by major histocompatibility antigens is more severe than GVHD evoked by mHAs.

Movement of cells in the immune system

The development of an immune response requires highly orchestrated patterns of cellular migration throughout the body tissues. The thymus and marrow are the primary lymphoid organs where T and B cells, respectively, are produced, and the spleen, lymph nodes, intestinal Peyer's patches, and other specialized sites such as bronchial and mucosal-associated lymphoid tissues are secondary lymphoid organs where lymphoid cells mature and initiate immune responses. During the afferent phase of the immune response, secondary lymphoid organs and tissues function as central meeting points where highly dynamic processes of cell movement allow responding T and B cells to encounter antigen-bearing APCs. Some APCs migrate to secondary lymphoid organs and tissues after acquiring antigen in the periphery, whereas others reside within secondary lymphoid organs and tissues and acquire antigen through direct infection, capture of free antigen, or engulfment of other antigen-bearing cells [10,11]. In the context of HCT, all recipient APCs can directly present alloantigens, and all donor-derived APCs have widespread access to recipient proteins containing alloantigen peptides that can be indirectly presented. During the efferent phase of the immune response, activated T cells leave the secondary lymphoid organs and tissues and migrate to the peripheral tissues, and activated B cells form germinal centers for production of antibody, memory B cells, and plasma cells. Movement of T cells across vascular endothelium into secondary lymphoid tissues during the afferent phase of the immune response and out of these tissues and into peripheral tissues during the efferent phase is regulated by selectins [12], integrins [13], chemokines [14], sphingosine-1-phosphate receptors [15], and certain vitamins.

Innate and adaptive immune responses

As discussed below, triggering of adaptive immunity to many pathogens is linked to prior activation of the innate immune system, which comprises both rapidly engaged antipathogen effectors and APCs that initiate adaptive immunity. The hypothesis that the immune system is endowed with receptors that can identify pathogen-associated molecular products (PAMPs) [16,17] was confirmed first in the identification of transmembrane Toll-like receptors (TLRs) [18]. This family of receptors can recognize a variety of PAMPs, including lipopolysaccharides (LPSs), DNA, RNA, and peptidoglycans [19a]. TLRs encounter ligands either at the cell surface or in endosomes. C-type lectin receptors (CLRs) are a second class of transmembrane cell surface glycoproteins that recognize PAMPS such as mannans and β-2-glucan [19b]. The cytoplasm also contains PAMP recognition systems. Nucleotide-binding oligomerization domain (NOD) leucine-rich-repeat (LRR)-containing receptors (NLRs) recognize a variety of PAMPs and the sequelae of cell stress and mediators of sterile inflammation such as urate and asbestos [20]. Rig-1-like receptors (RLRs) recognize viral RNA [21]. Finally, the cytoplasm can sense nucleic acids through mechanisms that activate signaling pathways converging on STING (stimulator of interferon genes). These detection systems lead to activation of NF-κB, generation of inflammatory mediators such as cytokines and interferons, and upregulation of costimulatory molecules. In sum, these downstream effects both endow the innate cells themselves with antipathogen properties and allow APCs to mold an adaptive T response appropriate to the invading organism or source of stress.

Barrier organs such as the intestinal tract, skin, and lung have highly sophisticated mechanisms that regulate interactions between the innate and adaptive immune systems, since they must be able to distinguish invading pathogens from commensal organisms that may also express PAMPs [22,23]. In the context of an alloimmune T-cell response, every APC is likely to be presenting some alloantigens, and engagement of any of these detection systems could affect the alloimmune response. Consistent with this hypothesis, polymorphisms of some of these receptors in humans have been associated with transplant outcomes, including GVHD. In murine models, alloimmune T-cell responses can occur when APCs lack the ability to respond to any one of the major classes of these receptors, indicating that no single innate receptor system is required [24].

Regulation of natural killer-cell responses

Natural killer (NK) cells are a component of the innate immune system [25] (see Chapter 11). These cells emerge from the marrow, develop in lymph nodes and tonsils, and express CD56 and CD16 but not CD3. NK cells mediate their effects through cytotoxic activity and production of cytokines such as interferon-gamma (IFN-γ) [26,27], tumor necrosis factor-alpha (TNF-α) [28], and granulocyte–macrophage colony-stimulating factor (GM-CSF). NK cells express both activating and inhibitory cell surface receptors, and NK cell function is regulated through the overall balance of activation and inhibitory signals mediated through these receptors (Figure 9.2) [29]. The importance of NK cells for transplantation comes from their ability to recognize MHC class I alloantigens [30].

Human NK cells collectively express a variety of killer lectin-like receptors associated with CD94, killer-cell immunoglobulin-like receptors (KIRs), and natural cytotoxicity receptors. Murine NK cells have killer lectin-like receptors but not KIRs. Individual NK cells express a limited number of receptors through stochastic mechanisms. Receptors with short cytoplasmic tails associate with signaling protein molecules containing immunoreceptor tyrosine-binding activation motifs (ITAMs) that activate NK cells. Receptors with long cytoplasmic tails containing immunoreceptor tyrosine-binding inhibitory motifs (ITIMs) inhibit activation of NK cells. Most lectin-like receptors and KIRs bind to MHC class I ligands. NKG2D is an unusual lectin-like activating receptor that recognizes the MHC class I-like molecules MIC-A and MIC-B and other molecules that are expressed in response to cellular stress [31]. Natural cytotoxicity receptors activate NK cells in response to infection, but the ligands for these receptors have not been well defined.

During their development, NK cells are “educated” to acquire functional competence and self-tolerance such that they do not respond to cells that have normal expression of the self-MHC class I molecules that function as ligands for inhibitory receptors, except when signals from activating receptors such as NKG2D overwhelm the effect of inhibitory signals [29,32–34]. Under certain circumstances, donor NK cells can recognize malignant cells in the recipient and contribute to a GVLE, either because malignant cells in an MHC-mismatched recipient lack expression of donor MHC class I molecules that function as ligands for inhibitory receptors on donor NK cells, or because the expression of activating ligands by malignant cells overwhelms the effect of inhibitory ligands.

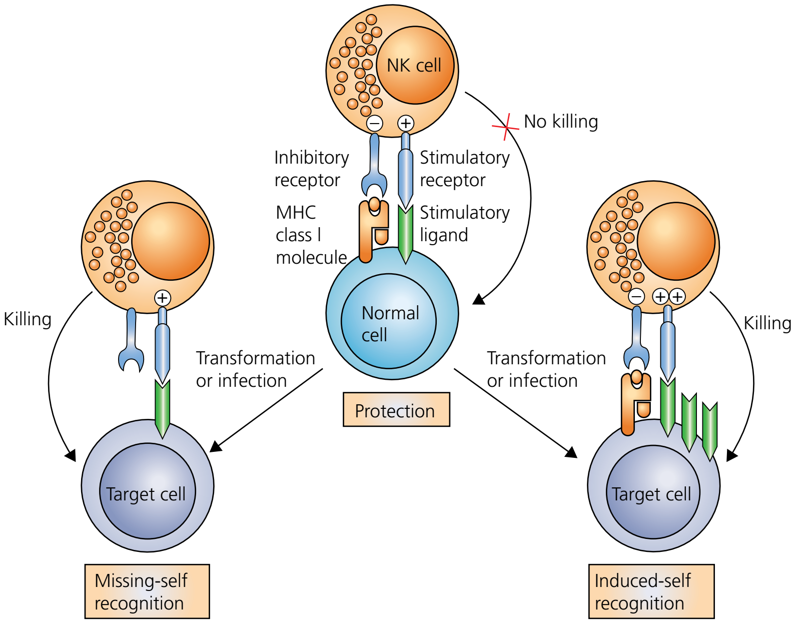

Figure 9.2 NK cell activation. NK cells express both inhibitory and stimulatory or activating receptors. NK cells do not kill normal cells, because binding of self-MHC class I molecules to inhibitory receptors on the NK cell override any activating signals originating from stimulatory ligands on normal cells. NK cells can kill target cells that are altered by infection or malignant transformation either because expression of self-MHC class I molecules is lost or downregulated (left side) or because expression of stimulatory ligands is increased (right side). Self-tolerance and antigen recognition by T cells

Molecules used for recognition of antigens

Adaptive immune responses are orchestrated and mediated by T and B lymphocytes. In T cells, immune recognition is mediated by the T-cell receptor (TCR); in B cells, immune recognition is mediated by immunoglobulin molecules. In general, each T cell and B cell expresses a single type of receptor for recognizing antigen epitopes. Both types of cell utilize similar mechanisms for generating an enormous diversity of clonally distributed receptors. This diversity is generated initially by somatic rearrangements that link *V* (variable), *D* (diversity), and *J* (joining) segments in various combinations to encode a large repertoire of distinct clonally distributed receptors among T cells and B cells. TCRs recognize peptide antigens presented by MHC molecules, whereas B cell receptors and secreted immunoglobulin (Ig) recognize proteins free of any presenting molecule. High-throughput sequencing of TCR and Ig gene rearrangements can characterize the clonal repertoire of T and B cells and may help elucidate the biology of these responses in immunologic reactions such as GVHD and GVLEs.

TCR signaling

Signal transduction in T cells leads to transcriptional activation of numerous genes by activator protein-1 (AP-1), nuclear factor-kappa B (NFκB), and nuclear factor of activated T cells (NF-AT) [35]. In broad outline, the process begins by the formation of "immunologic synapses" that concentrate TCR–CD3 complexes, CD2, and CD4 or CD8 within small regions of the membrane [36–38]. Molecules associated with the cytoplasmic domains of TCR–CD3 complexes and CD4 or CD8 assemble as a scaffold that initiates a cascade of protein tyrosine phosphorylation events leading to activation of phospholipase Cγ. Phospholipase Cγ cleaves phosphatidylinositol 4,5-diphosphate (PIP_2) in the plasma membrane to form diacylglycerol (DAG) and inositol 1,4,5-triphosphate (IP_3). DAG activates protein kinase Cθ, leading to translocation of NFκB from the cytosol to the nucleus. In the nucleus, NFκB family members function as transcriptional regulators for numerous cytokine genes, including *IL-2*. DAG also activates the p21 Ras pathway, leading to activation of Fos, which functions as a component in the AP-1–promoter complex for transcription of *IL-2* and other genes involved in activation. IP_3 releases Ca^{2+} from intracellular stores and allows influx of extracellular Ca^{2+}, thereby activating calcineurin, an enzyme with serine/threonine phosphatase activity. Activated calcineurin dephosphorylates NF-AT, which then translocates from the cytosol to the nucleus, where it activates transcription in conjunction with AP-1. The immunosuppressive drugs cyclosporine and tacrolimus bind to intracellular proteins, forming drug–protein complexes that inhibit the enzymatic activity of calcineurin, thereby preventing activation of NF-AT and interfering with signal transduction in T cells after stimulation with antigen.

Selection of T cells in the thymus

Precursors destined to become T cells originate from hematopoietic stem cells that migrate to the thymus (Figure 9.3). T-cell maturation in the thymus "positively" selects T cells that have receptors with modest affinity for self-MHC–peptide complexes while deleting T cells that have receptors with high affinity for self MHC–peptide complexes ("negative selection") [39–41]. T cells with receptors that fall below the affinity threshold for positive selection die by "neglect." The process of "positive selection" is mediated primarily by thymic cortical epithelial cells. Negative selection is mediated by marrow-derived dendritic cells (DCs) and by thymic medullary epithelial cells. In particular, thymic medullary epithelial cells have "promiscuous" expression of proteins that are "tissue-specific" for organs outside the thymus, thereby eliminating T cells that would be self-reactive in the periphery. Interactions with thymic epithelial cells can also cause developing T cells to become nonresponsive or "anergic" to self-MHC molecules. As an alternative fate, T cells that have TCRs with high affinity for self can be induced to express the transcription factor FoxP3. These cells then differentiate into regulatory T (Treg) cells that suppress T-cell immune responses in the periphery [42]. Negative selection, induction of non-responsiveness, and generation of Treg cells represent the principal "central" mechanisms for establishing self-tolerance (see Chapter 12).

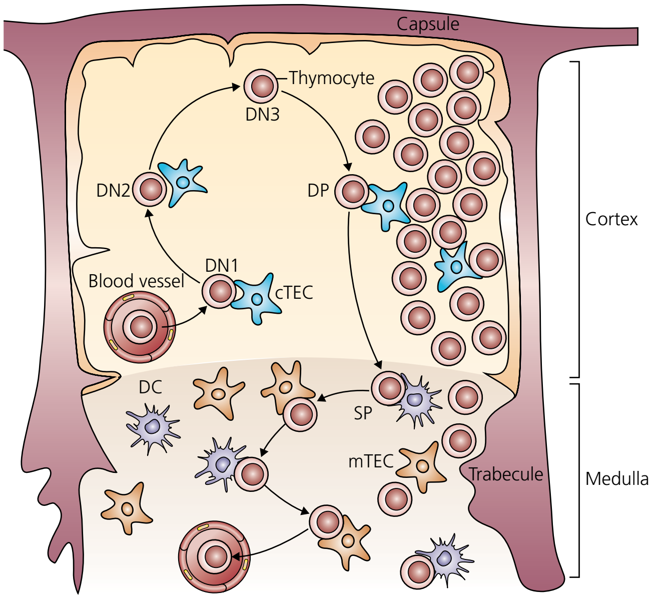

Figure 9.3 Thymic selection. Marrow-derived progenitors enter the thymus through blood vessels and go through three stages of development in the cortex, beginning as "double-negative" (DN) cells lacking expression of either CD4 or CD8 and ending as "double-positive" (DP) cells expressing CD4, CD8, and T-cell receptor β (TCRβ). DP cells with TCRβ receptors that bind to MHC molecules on cortical epithelial cells are positively selected, whereas those lacking TCRβ receptors that bind to MHC molecules on cortical epithelial cells die through neglect. Positively selected DP cells lose expression of either CD4 or CD8, and the "single-positive" (SP) cells expressing either CD4 or CD8 move to the medulla, where they interact with medullary thymic epithelial cells (mTEC) and dendritic cells (DC). SP cells with TCR that have high avidity for MHC molecules on mTEC or dendritic cells die through negative selection. T cells that emerge from the thymus express TCR that have intermediate avidity for self-MHC molecules. Source: adapted from Klein et al. 2009 [40] with permission of Nature Publishing Group.

T-cell activation, effector differentiation, and effector functions

Activation of T cells by antigen-presenting cells

DCs, B cells, macrophages and basophils are the major classes of hematopoietic cells that can prime naïve T cells and activate memory T cells. DCs comprise a heterogeneous collection of different cell types that have in common the expression of CD11c and MHC class II molecules. DC subsets arise from different bone marrow-derived precursors through distinct developmental pathways, frequently further influenced by inflammation [43,44]. DC subsets reside in different locations (e.g., peripheral tissues versus primary or secondary lymphoid organs), and each organ is endowed with its own mix of DCs. Langerhans cells are a subset of epidermal DCs that express langerin. Unlike conventional DCs, Langerhans cells arise locally from a pool of precursors that reside in the skin.

At sites of infection in peripheral tissues, DCs acquire antigen via endocytosis, pinocytosis, and direct infection and then migrate to lymph nodes. Upon arrival in the lymph nodes, DCs directly present antigen to T cells or transfer antigen to other APCs for presentation. Interaction between TCR and MHC–peptide complexes requires close apposition between T cells and APCs [45]. Adhesive interactions exemplified by the respective binding of CD11a/CD18 [leukocyte function-associated antigen-1 (LFA-1)] and CD2 on T cells with CD54 (intracellular adhesion molecule-1) and CD58 (LFA-3) on APCs help to overcome the repulsive forces created by the net negative surface charge of these cells [13]. These molecules also exhibit outside-in signaling, which contributes to T cell activation. Full activation of T cells, including those generating an alloimmune response, requires interactions of a sufficient avidity between the TCRs on T cells and MHC–peptide complexes on APCs [46]. TCR signaling induces a higher affinity conformation of LFA-1, further cementing the interface between T cells and APCs. Engagement between CD28 and its ligands CD80 and CD86 promotes the production of IL-2. CD28 signaling is particularly important for activation of naïve CD4 cells and activation of naïve CD8 cells against lower avidity antigens. IL-2 stimulates proliferation of activated T cells and the differentiation of CD4 cells into various effector T-cell subsets (see below) [47]. IL-2 also stimulates the differentiation of CD8 cells into effectors and their transition into memory cells, and it plays a crucial role in the maintenance of Treg cells.

As demonstrated in murine GVHD models [48–50], initial activation of naïve donor T cells occurs predominantly in secondary lymphoid organs of the recipient. Since the frequency of T cells for a given peptide–MHC combination is very low, specialized mechanisms have evolved to increase the probability that T cells of appropriate specificity have sufficient opportunity to establish contacts with relevant antigen-bearing APCs [51,52]. Successful interactions are promoted by recirculation of T cells both within lymphoid organs on a reticular cell network and between lymphoid organs in blood and lymph. Further, activated APCs release soluble attractants for T cells. Optimal T-cell activation may require recruitment of accessory cells. For example, CD8$^+$ T-cell responses are substantially modified by concomitant local CD4$^+$ T-cell activation, and NK cells can influence the function of APCs, thereby influencing the T-cell response.

T-cell differentiation

T-cell activation and differentiation are not based entirely on TCR signaling. Rather, T-cell activation and differentiation reflect the summation of graded signals from many receptors in response to ligands from APCs and other accessory cells [53,54]. The outcome depends on the strength, duration, timing, and frequencies of these signals. This complex combinatorial signaling provides sufficient information to generate a wide array of T-cell responses. A simplified framework for naïve T-cell activation involves signaling through three types of receptors: TCR, receptors engaged by costimulatory molecules on APCs (Table 9.2) [55–58], and cytokine receptors [59,60]. For CD4 cells, integration of these signals results in the generation of multiple different types of T cells, including T helper (T_H) 1, T_H2, T_H17, T follicular helper (T_{FH}) cells, Tr1, T_H9, and induced FoxP3$^+$ Treg cells. Each subset produces a characteristic set of dominant cytokines. For many subsets, CD4$^+$ T-cell differentiation relies upon activation in the presence of a distinct set of cytokines and induction of a specific transcription factor (Figure 9.4) [61,62]. For example, IFN-γ, IL-12 and IL-18 induce T-bet expression and T_H1 differentiation. IL-4 and IL-33 induce GATA3 expression and T_H2 differentiation. IL-1 and IL-6 induce RORγT expression and T_H17 differentiation. TGF-β induces FoxP3 expression and induces regulatory T-cell differentiation. Frequently, the activity of one type suppresses the development of another [63]. Plasticity adds to the complexity, in that cells can have a mixed phenotype or revert from one type to another [64]. Naïve CD8 cells can also differentiate into some of these analogous subsets. Regulation of CD8 responses, however, seems to be more directed towards influencing differentiation between effector and memory T cells [65]. After initial antigen activation, CD8 cells proliferate vigorously and then die off, with a smaller number of CD8 cells persisting long term as memory cells [66]. Continued inflammation promotes short-term effector differentiation. With less inflammation, activated CD8 cells are more likely to differentiate as memory cells.

Costimulation through interactions of CD28 with CD80 and CD86 is critical for initial activation of T cells, but later costimulation further shapes the character and magnitude of T-cell responses. Costimulatory molecules generally belong to the CD28 or TNF

Table 9.2 Receptors and ligands involved in costimulation

Receptor on T cells	Molecular superfamily	Stage of initial expression by T cells	Ligands on antigen-presenting cells	Functional effect on T cells	Functional effect on antigen-presenting cells
CD28	Ig	Naïve	B7-1/B7-2 (CD80/CD86)	Stimulation	Unknown
CD27	TNF	Naïve	CD70	Stimulation	Unknown
CD40L (CD154)	TNF	Early activation	CD40	Unknown	Stimulation
CTLA4 (CD152)	Ig	Early activation	B7-1/B7-2 (CD80/CD86)	Inhibition	Unknown
ICOS	Ig	Early activation	B7h	Stimulation	Unknown
PD-1	Ig	Early activation	PD-L1/PD-L2	Inhibition	Unknown
CD160	Other	Effector or memory	HVEM	Inhibition	Unknown
HVEM	TNF	Effector or memory	LIGHT	Stimulation	Unknown
OX40 (CD134)	TNF	Effector or memory	OX40-L	Stimulation	Unknown
GITR	TNF	Effector or memory	GITR-L	Stimulation	Unknown
4-1BB (CD137)	TNF	Effector or memory	4-1BBL	Stimulation	Unknown
CD30	TNF	Effector or memory	CD30L	Stimulation	Unknown
TIM-1	TIM	Effector or memory	TIM-4	Stimulation	Unknown
TIM-2	TIM	Effector or memory	Sema4a	Inhibition	Stimulation
TIM-3	TIM	Effector or memory	Galectin-9	Inhibition	Stimulation

CTLA4, cytotoxic T lymphocyte antigen-4; ICOS, inducible costimulatory molecule; PD, programmed cell death; HVEM, herpes virus entry mediator A; GITR, glucocorticoid-induced TNF-related protein; TIM, T-cell Ig domain and mucin domain family; Ig, immunoglobulin; TNF, tumor necrosis factor; LIGHT, ligand for herpes virus entry mediator; Sema, semaphorin; suffix R, receptor; suffix L, ligand.

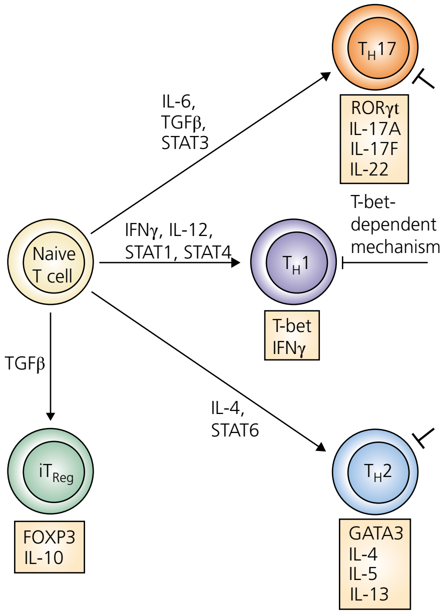

Figure 9.4 T helper cell differentiation. After activation, naïve CD4 cells can differentiate into a variety functionally distinct types of effector T cells, depending on the dominant environmental cytokines that drive characteristic intracellular signaling through signal transducer and activator of transcription (STAT) molecules. Activation dominated by interferon-γ (IFN-γ) and interleukin (IL)-12 drives STAT 1 and STAT4 signaling and produces type-1 T helper cells (T_H1) cells by inducing expression of the transcriptional regulator T-bet. T_H1 cells produce IFN-γ and play a prominent role in cell-mediated immunity. Activation dominated by IL-4 drives STAT6 signaling and produces type-2 T helper cells (T_H2) by inducing expression of the transcriptional regulator GATA binding protein 3 (GATA3). T_H2 cells produce IL-4, IL-5 and IL-13 and play a prominent role in humoral immunity. Activation dominated by IL-6 and transforming growth factor β (TGFβ) drives STAT3 signaling and produces T helper 17 (T_H17) cells by inducing expression of the transcriptional regulator retinoic acid receptor-related orphan receptor-γt (RORγt). T_H17 cells produce IL-17 and IL-22 and play a prominent role in cell-mediated inflammation. Activation dominated by TGFβ produces induced T regulatory (iTreg) cells by inducing expression of the transcriptional regulator forkhead box P3 (FoxP3). iTreg cells produce IL-10 and function as regulators that dampen immune responses. receptor families and can be classified according to their stimulatory or inhibitory effects on T-cell survival, proliferation and effector function [58]. Because resting T cells express CD28, they are susceptible to early regulation by interactions with CD80 and CD86. In contrast, other receptors for costimulatory molecules such as CD27, ICOS, OX40, and 4-1BB are expressed only after initial activation. T cells can also condition APCs through engagement of costimulatory receptors [67]. In particular, CD40L on CD4 cells activates APCs and signals immunoglobulin class switching. Some costimulatory receptors deliver negative signals to T cells, as discussed further below [68].

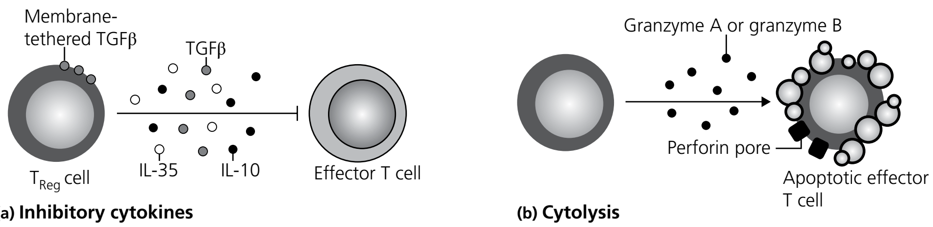
Costimulatory molecule and cytokine receptor signaling

Costimulation signals mediated through CD28 contribute to full activation of T cells. CD28 signaling activates phosphatidylinositol 3-kinase (PI3K), an enzyme that converts PIP_2 to phosphatidylinositol 3,4,5-triphosphate (PIP_3). In the plasma membrane, PIP_3 recruits both phospholipase Cγ and the cytoplasmic tyrosine kinase that activates phospholipase Cγ (see above). Signaling through PIP_3 or Ras activates the mammalian target of rapamycin (MTOR) pathway. MTOR is a serine–threonine kinase that promotes translocation of NFκB to the nucleus, thereby augmenting expression of IL-2 and IL-2R. MTOR exists in at least two distinct complexes. The immunosuppressive drug sirolimus binds to an intracellular protein, forming a drug–protein complex that inhibits one of these complexes. By dampening signal transduction through PI3K and MTOR, sirolimus inhibits certain costimulation pathways and cytokine responses [69], with greater functional inhibition of effector T cells compared with Treg cells [69,70].

Many cytokine receptors have a heterodimeric structure. In some cases, a common chain is used as a partner for several different types of cytokine receptors. For example, receptors for IL-2, IL-4, and IL-15 have the same γc chain as one member of the heterodimer. Binding of a cytokine to the two chains of the receptor brings together the respective dimer components in the plasma membrane. This dimerization activates Janus kinase (JAK) domains in the cytoplasmic tails of the dimeric partners. Phosphorylated JAK domains recruit and activate signal transducers and activators of transcription (STATs). Phosphorylated STAT dimers translocate to the nucleus where they initiate gene transcription.

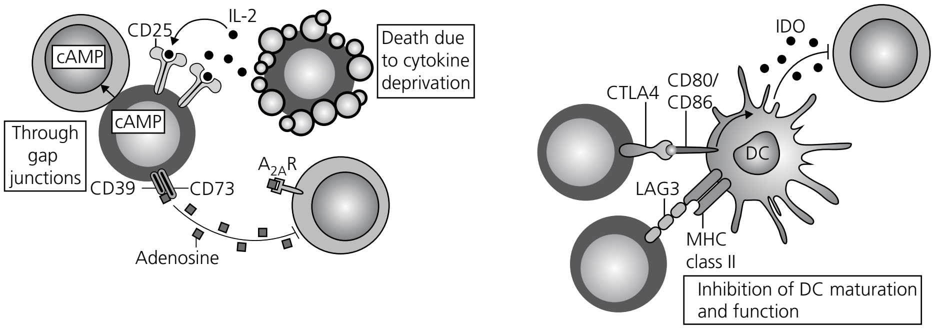
Proinflammatory T-cell effector functions

A detailed description of the functions of each type of T cell that can be generated after antigen exposure is beyond the scope of this chapter and has been the subject of many reviews [64,71–73]. TCRs on CD4 cells are activated only by MHC class II$^+$ cells, and MHC class II expression is far more restricted than MHC class I expression. MHC class II molecules are expressed on APCs, and expression is upregulated by APC activation. Therefore, T_H CD4 cells are well equipped to orchestrate actions of other immune cells [53,74,75]. T_H1 cells, which produce IFN-γ, mediate classical macrophage activation and promote specific types of antibody responses. T_H1-derived IFN-γ elaborated after activation in inflamed tissues can also have bystander effects on cells that do not express MHC class II molecules [27]. Synchronous activation of many CD4$^+$ T cells, which may occur after allogeneic HCT, can induce systemic toxicity through the elaboration of inflammatory cytokines such as IFN-γ and TNF-α. T_H2 cells produce IL-4 and IL-5, promoting IgG1 and IgE responses and helping to recruit eosinophils that are required for antiparasite immunity. T_H17 cells produce IL-17, a cytokine that stimulates neutrophil responses to bacteria and fungi. T_H17 cells have also been implicated in models of inflammatory bowel disease and autoimmune encephalitis. T_{FH} cells promote germinal center reactions and affinity maturation of B-cell receptors. Non-hematopoietic cells can upregulate expression of MHC class II molecules, for example in response to IFN-γ. Through this mechanism, CD4$^+$ T cells can cause direct damage to non-hematopoietic cells. CD4$^+$ T cells can have cytolytic activity mediated through expression of the TNF-family ligands for Fas, TNF-R1, and TRAIL-R and through release of granules containing perforin and granzymes. CD8$^+$ T cells can interact with a wider array of cells, since MHC class I molecules are expressed on nearly all nucleated cells. CD8$^+$ T cells have a critical role in mediating antiviral responses by killing virus-infected cells through engagement of death receptors and the release of granules containing perforin and granzymes [66,76]. CD8$^+$ T cells also produce proinflammatory cytokines, including IFN-γ and TNF-α.



(a) Inhibitory cytokines

(b) Cytolysis



(c) Metabolic disruption

(d) Targeting dendritic cells

Figure 9.5 Mechanisms of T-regulatory cell function. T-regulatory cells (Treg cells) can dampen immune responses (a) by producing cytokines such as transforming growth factor β (TGFβ), interleukin (IL)-35, or IL-10 that inhibit effector T cell responses, (b) by killing effector cells through granzyme or perforin-mediated mechanisms, (c) by metabolic disruption of effector cells through competition for IL-2, delivery of cyclic adenosine monophosphate (cAMP), or signaling through adenosine 2A receptors ($A_{2A}R$) after release of adenosine via CD39- or CD73-mediated mechanisms, and (d) by interfering with maturation and function of dendritic cells when lymphocyte activation gene 3 (LAG3) on Treg binds to MHC class II molecules on dendritic cells, and by inducing dendritic cells to inhibit effector function through production of indoleamine 2,3-dioxygenase (IDO) when cytotoxic T lymphocyte antigen-4 (CTLA4) on Treg binds to CD80 and CD86 on dendritic cells. IDO causes depletion of tryptophan, which inhibits effector T-cell function. Source: adapted from Vignali et al. 2008 [87] with permission of Nature Publishing Group.

Peripheral tolerance and regulation of T-cell responses

Despite the redundancy of mechanisms for inducing central tolerance, some self-reactive T cells emerge from the thymus and migrate to the periphery. Therefore, mechanisms must exist to diminish the risk that these cells will be activated and expanded sufficiently to cause autoimmunity [77]. In addition, excessive tissue damage by cells with low affinity for self must be avoided during the response to infection. The immune system has evolved strategies at nearly every step of the T-cell response to diminish these risks. For example, TCR activation itself is highly regulated, and phosphatases that diminish TCR signaling are activated almost immediately after TCR engagement [78]. As a mechanism for maintaining peripheral tolerance, presentation of self-antigens by DCs outside the thymus and by lymph node stromal cells in the absence of innate alarm signals can result in proliferation followed by deletion or anergy [44,79,80].

Activated T cells also coordinately upregulate inhibitory receptors [58,81]. The CD28 family member CTLA4 is a prototypical inhibitory receptor that is induced early after T-cell activation. Compared with CD28, CTLA4 has higher affinity for CD80 and CD86. The importance of CTLA4 in regulating T-cell responses is evident from the autoimmunity that occurs when it is genetically absent or when binding is blocked by exogenous agents. Fas on T cells also downregulates T-cell responses, and Fas- or FasL-deficient mice and humans have autoimmune syndromes [82]. PD-1, another CD28 family member, inhibits T-cell responses through engagement of its ligands PD-ligand 1 and PD-ligand 2 (also known as B7H1 and B7DC, respectively). The absence of PD-1 causes an autoimmune syndrome that is less severe than that caused by the absence of CTLA4. Reagent-based blockade of PD-ligand 1 can induce antitumor T-cell responses, and experimental systems have demonstrated that both PD-1 and CTLA-4 help to regulate GVHD. TGF-β and B and T lymphocyte attenuator (BTLA) also downregulate T-cell responses. Chronic antigen stimulation leads to a progressive state of T-cell hyporesponsiveness called exhaustion. Several receptors, including PD-1, TIM-3, and LAG-3, contribute to T-cell exhaustion, and their blockade can partially restore T-cell function. PD-1, TIM-3, BTLA, and CTLA4 all regulate alloreactive T-cell responses.

T cells with primary regulatory functions also downregulate T-cell responses and contribute to tolerance [83–86]. FoxP3-dependent thymus-derived Tregs help to maintain tolerance, and their genetic absence or deletion results in severe autoimmunity. FoxP3-expressing Treg cells can also be induced from conventional T cells. This differentiation is provoked only by specific subsets of DCs. The exact mechanisms whereby Tregs act in vivo are not fully elucidated, but evidence supports roles for Treg-derived IL-10, TGF-β, and cytotoxic mechanisms involving perforin and granzymes (Figure 9.5) [87]. Finally, activated T cells can differentiate into FoxP3-negative cells with regulatory function, characterized by expression of IL-10 [85,88].

T-cell memory

T cells exhibit primary and secondary immune response in vivo [63,66,89]. "Primary" responses occur when immunologically "naïve" cells first encounter a specific antigen. The immune response after an initial encounter with antigen develops during a period of approximately 1 week and results in the expansion of specific clones of effectors having TCRs that recognize the antigen.

This initial expansion is followed by clonal contraction. After stimulation of naïve T cells, asymmetric cell division differentiates effector and memory T-cell fates. Memory T cells can be divided into at least two distinct subsets [90,91]. The "central" memory population resembles the antigen-inexperienced naïve T-cell population, migrates preferentially through lymphoid tissue, and is long lived, whereas the "effector" memory population resembles the antigen-experienced effector T-cell population, migrates preferentially in non-lymphoid tissues, and is short lived [92]. Resident memory cells are generally characterized by selection for high TCR affinity, increased expression of adhesion molecules, and altered migratory patterns with distinctive cytokine production and response profiles [93]. Memory cells remain poised to respond quickly after a repeated encounter with antigen. "Secondary" responses by memory cells develop during a period of several days and show greater intensity than the original primary response. CD4 cells are required for maintenance of CD8 memory cell survival and function [94]. IL-7 has an important role in survival of memory CD8 cells, while IL-15 is necessary for proliferation of memory CD8 cells [95].

Selection of donors for allogeneic HCT

The immunogenetic relationship between the donor and recipient profoundly influences the outcome of HCT, much more so than with solid organ transplants [2]. Within the constraints of current practice, however, these differences are most apparent when analyzing immunologic outcomes, such as graft rejection and the incidence and severity of GVHD, and are less apparent when analyzing disease-free survival (DFS). Since MHC matching avoids activation of T cells by major histocompatibility antigens, the best results are seen after transplantation from HLA-genotypically identical sibling donors, but only 30% of patients have such a donor. Some patients without an HLA-identical sibling have an HLA-haploidentical family member with limited mismatching between the non-shared haplotypes (see Chapter 44). Previous studies have shown that patients receiving an HLA-haploidentical transplant incompatible for a single HLA-A, -B, or -DR antigen can have DFS similar to that of patients with marrow from HLA-genotypically identical sibling donors, although HLA mismatching increases the risk of GVHD. Patients receiving transplants incompatible at two or three of these loci have a significantly lower probability of survival when conventional immunosuppressive regimens are used after HCT. In this situation, problems related to GVHD can be overcome by removing T cells from the graft or by giving cyclophosphamide after transplantation to eliminate T cells that are activated after they recognize recipient alloantigens.

HCT from HLA-phenotypically matched unrelated donors or cord blood donors is an alternative for patients who lack a donor in the family (see Chapters 45 and 39). Unrelated HCT has been made feasible by the development of large registries of HLA-typed individuals and cryopreserved cord blood units available to serve as a source of hematopoietic cells. With registries currently available in the United States and in other countries, it is now possible to identify an HLA-A, B-phenotypically matched DRB1 allele-matched unrelated donor for at least 70% of white persons. HLA alleles are more diverse in Hispanic and black populations, and success rates for matching unrelated donors in these populations are lower than in white persons. If a single HLA-A, -B, or -DRB1 mismatch were allowed, then it would be possible to identify donors for many more patients. In certain circumstances, DFS for patients with HLA-A, -B, -C, -DRB1, and DQB1 allele-matched unrelated donors may be comparable to that for similar patients with HLA-genotypically identical sibling donors (see Chapter 45).

Outcomes influenced by genetic disparity between the donor and recipient

Engraftment

Graft rejection after HCT may be manifested as either the lack of initial engraftment or the development of pancytopenia and marrow aplasia after initial engraftment. In humans, rejection, drug toxicity, sepsis, and certain viral infections can all cause graft failure. The key findings that support a diagnosis of rejection in a patient with graft failure are the absence of donor cells and the presence of recipient T cells. The durable persistence of donor cells makes rejection unlikely, even when recipient T cells can be detected.

Experiments in animal models have demonstrated that antibody, NK cells, and T cells of the recipient can all mediate allogeneic marrow graft rejection [96]. Mice with antibody against major histocompatibility antigens of the donor reject donor cells within 3 hours after HCT. NK-mediated rejection does not involve immunologic priming and occurs within 1–2 days after transplantation [30]. The effectors have a life span of less than 1 week but are highly resistant to irradiation. In rodents, NK-mediated rejection can be overcome by treatment of the recipient with cyclophosphamide (CY) or with antibodies that deplete NK cells in the recipient before the transplant. Because NK precursors are sensitive to irradiation, NK-mediated rejection can also be overcome by split-dose irradiation of the recipient, with an interval of 1 week between two irradiation exposures. Rejection mediated by unprimed T cells does not occur until 7–8 days after transplantation.

Rejection by T cells can be enhanced by priming or transfusion-induced sensitization before the transplant. T-cell effectors have a longer life span than NK cells and are generally more sensitive to radiation than NK cells. The increased risk of rejection associated with transfusion-induced sensitization and the decreased risk of rejection associated with the use of higher levels of total body irradiation (TBI) before the transplant clearly implicate recipient T cells as effectors that can mediate HCT rejection in humans. In support of this hypothesis, recipient-derived T cells with antidonor HLA-specific cytotoxic activity have been isolated from the blood of patients with graft failure after HLA-mismatched HCT. A delayed onset of rejection and an occurrence of rejection after grafting from an HLA-identical donor would argue against a role for NK cells in causing rejection. NK-mediated rejection also seems unlikely among patients who have received high-dose CY before the transplant, if it is assumed that this agent has similar effects on human and murine NK cells.

Mechanisms by which recipient NK cells or T cells might cause marrow graft rejection have not been fully elucidated. Although it seems intuitively obvious that cell-mediated cytotoxicity might be involved, recipients deficient in perforin, granzyme B, or FasL function can reject an allogeneic marrow graft. These results indicate redundancy in the mechanisms by which recipient effectors can kill donor hematopoietic cells, as also shown to be the case in GVLEs (see below). This hypothesis was supported by observations that NK cells from certain strains of mice could not mediate marrow graft rejection when perforin- and FasL-mediated mechanisms of cytotoxicity were both absent. Because hematopoietic stem cells do not express Fas under steady-state conditions, any potential involvement of a FasL-mediated mechanism in marrow graft rejection would require the induction of Fas expression, possibly through exposure to IFN-γ or TNF-α. Alternatively, TNF-α released by cytotoxic T lymphocytes (CTLs) or NK cells could have a direct suppressive or cytotoxic effect on hematopoietic stem cells. Graft rejection by CD8 cells after immunization of the recipient against donor alloantigens appears to be mediated by mechanisms other than perforin or FasL.

The risk of graft failure depends on the degree of genetic disparity between the donor and recipient. In particular, graft failure after unrelated marrow transplantation has been associated with HLA class I mismatching. The association between HLA class I disparity and graft failure has been observed primarily among patients with chronic myelogenous leukemia (CML) and other diseases that are not treated with intensive chemotherapy before referral for transplantation. The risk of graft rejection is also greatly increased by transfusion- or pregnancy-induced alloimmunization of the recipient against the donor before the transplant. Alloimmunization presumably occurs when a fetus or transfusion donor happens to have transplantation antigens in common with the transplant donor. Sensitization of the recipient against some alloantigens can be detected by the presence of antibodies that recognize donor T cells or B cells. After sensitization, rejection may be caused either by memory T cells that survive the conditioning regimen or possibly by antibody-mediated destruction of donor cells [97].

The use of more intensive conditioning regimens can reduce the risk of rejection by eliminating a greater proportion of recipient T cells before the transplant, but this approach cannot decrease the risk of antibody-mediated rejection. Post-transplant administration of immunosuppressive agents such as methotrexate and possibly cyclosporine decreases the risk of rejection by interfering with the function of recipient cells that survive the conditioning regimen. Donor T cells can also play a critical role in preventing rejection by recognizing any surviving recipient T cells and eliminating them primarily through a perforin-mediated cytotoxic mechanism. Under certain experimental conditions, donor NK cells and T cells that do not cause GVHD can prevent rejection. Other experiments have shown that precursor-plasmacytoid DCs of the donor can facilitate marrow engraftment.

Acute GVHD

The development of GVHD is a major determinant of outcome after allogeneic HCT (see Chapters 83 and 84 and [1,98–100]). Acute GVHD is caused by mature donor T cells that recognize recipient tissues as "non-self" and cause tissue damage through direct cytolytic mechanisms and indirectly through the release of cytokines and perhaps through the activation of other cells such as macrophages. GVHD can be elicited by T cells that recognize MHC alloantigens and mHAs of the recipient. In the presence of an MHC mismatch, the high precursor frequency of alloreactive donor T cells causes an increased risk of GVHD, but MHC alloantigens can be presented only by recipient cells. Soon after HCT, most of the recipient hematopoietic APCs that trigger GVHD are replaced by donor cells that lack the MHC mismatch. Results in experimental systems have suggested that the responding donor T cells may need continued stimulation by hematopoietic APCs in order to sustain full GVHD activity, and the initial activation of T cells that recognize the MHC mismatch can be followed by some recovery as recipient APCs disappear. Conversely, mHAs can be presented by either recipient or donor cells, and these antigens can be presented throughout the post-transplant period, even after recipient APCs have disappeared. Despite the large number of potential mHAs in any given donor–recipient pair, some are more effectively targeted than others. This "immunodominance" is also characteristic of T-cell responses against pathogens. The determination of whether any given antigen is immunodominant likely depends on the precursor frequency of reactive T cells and on the availability and tissue distribution of antigens.

Donor T cells are initially activated primarily in secondary lymphoid organs of the recipient. GVHD can occur in the absence of either the spleen or other secondary lymphoid organs [101]. Less severe GVHD is elicited in the absence of both the spleen and secondary lymphoid organs [49,50]. In this case, priming may occur in bone marrow. Naïve donor T cells express surface molecules that promote their recruitment to secondary lymphoid organs. CD62L and CCR7 promote entry to lymph nodes and localization to T-cell zones in the spleen and other secondary lymphoid organs, although their expression is not absolutely required to induce GVHD [50,102].

Activation of donor CD8 and $CD4^+$ T cells is driven initially by recipient APCs. Cross-presentation of recipient mHAs by MHC class I molecules on donor APCs does not generate a $CD8^+$ T-cell response that is sufficient to initiate histopathologic GVHD, but indirect presentation of recipient antigens by donor APCs can contribute to the later evolution of GVHD [103]. Early activation of donor $CD4^+$ T cells depends on recipient APCs, since donor-derived APCs are absent when donor T cells are transferred. Either recipient or donor APCs are sufficient to induce CD4-mediated GVHD against mHAs. Despite this redundancy, it is likely that recipient APCs are the initial activators, since it takes time for functional donor-derived APCs to emerge from the graft. This kinetic difference is demonstrated by the insufficiency of donor APCs in CD4-mediated mHA-disparate GVLE models in which the activation of donor CD4 cells by donor APCs occurs too late to control a large burden of rapidly proliferating malignant cells [104,105].

Substantial effort has been devoted to defining the recipient APCs that contribute to GVHD. Classical DCs, plasmacytoid DCs, and Langerhans cells are sufficient to initiate GVHD in MHC-mismatched models. For clinical purposes, the key question is the identification of recipient APC subsets that are required for induction of GVHD. In this regard, Langerhans cells, B cells, and plasmacytoid DCs are not required [106–108]. Surprisingly, GVHD was not prevented when classical DCs were profoundly ablated using multiple model systems and approaches, even with concomitant depletion of plasmacytoid DCs, B cells, and Langerhans cells [106,109]. Some of these experiments were done in systems where hematopoietic APCs were required, suggesting that other recipient hematopoietic APCs could be sufficient. In particular, $CD11c^-$MHC class II^+ myeloid cells, including macrophages, were not well targeted, and it remains to be tested whether these cell populations are sufficient. The possibility that miniscule numbers of targeted recipient APCs were sufficient to induce GVHD is difficult to exclude. Some results have resurrected the idea that non-hematopoietic cells in the recipient can initiate GVHD when functional hematopoietic APCs are absent [109–111]. Additional work has been carried out to identify the donor APCs that can activate alloreactive T cells. The results showed that donor conventional DCs were essential for presentation of recipient mHAs to donor T cells [103,112]. In humans, B cells may have an important role in promoting chronic GVHD (see below). The presence of antibodies recognizing male antigens in male recipients of female allografts correlated with chronic GVHD, and B-cell depletion can be an effective chronic GVHD treatment.

A current paradigm holds that APC activation by innate signals is required for optimal T-cell priming and effector differentiation [113].

It has long been advocated that translocation of LPS from the bowel lumen after conditioning is an essential first step in the development of GVHD. LPSs, and perhaps other TLR ligands, were proposed to function at least in part by activating recipient APCs. More recent work, however, demonstrated that the development of GVHD is not impaired when recipient APCs cannot respond to TLR ligands, IL-1, or type I IFNs [24]. TBI enriches for recipient APCs with higher levels of CD80 and CD86, but it has not been established that this maturation is essential for the development of GVHD, and activation of alloreactive T cells can occur in the absence of any recipient conditioning. In contrast to the lack of major phenotypic changes in GVHD when recipient APCs cannot be activated by TLR, IL-1, or type I IFN, recent work has shown that both complement and ATP may activate APCs that initiate GVHD.

Compared with naïve T cells, memory phenotype T cells have a reduced ability to cause GVHD in mice. In multiple donor–recipient strain pairings, effector memory cells cause little or no GVHD. Data are mixed for central memory T cells, with some studies showing they cause no GVHD and others showing that they cause less severe GVHD compared with naïve T cells [114]. The failure of effector memory CD4 cells to cause GVHD cannot be explained by the absence of CD62L expression and their relative inability to traffic to lymph nodes, since the forced expression of CD62L on effector memory cells did not restore their ability to cause GVHD. Likewise, naïve T cells can cause GVHD in the absence of lymph nodes. Recent data suggest that the reduced capacity of effector memory T cells to cause GVHD relates both to TCR repertoire-dependent and -independent properties [115,116].

During the efferent phase of the disease, activated donor T cells migrate to target organs where they cause tissue injury in the skin, liver, and gastrointestinal tract. Chemokines expressed in target tissues bind to chemokine receptors on T cells and help attract T cells into these tissues. Activated T cells from both the CD4 and CD8 subsets produce proinflammatory cytokines, and both subsets generate CTLs. No single effector mechanism can account for the entire clinical spectrum of acute GVHD (see Chapters 13 and 83). In some patients, the disease presents as a syndrome of high-grade fever, confluent erythematous rash, and vascular leak with pulmonary infiltrates and edema during the first 10 days after the transplant. In this situation, the disease can be viewed appropriately as a "cytokine storm" that generally shows striking improvement after treatment with high-dose glucocorticoids. In most patients, however, the disease presents in much less dramatic fashion, with a slowly progressive morbilliform rash or with anorexia, nausea, and vomiting. The role of cytokine storm in these more typical cases of acute GVHD without overt systemic toxicity remains to be determined.

Cytokines play complex roles in the pathogenesis of GVHD, and much effort has been devoted to determining which cytokines and which T_H subsets contribute to GVHD [117,118]. In mice with GVHD, IFN-γ-producing T cells dominate, with much smaller numbers of T_H2 cells and even fewer IL-17-producing cells. Data from experiments with T cells deficient in specific cytokines or with reagent-based cytokine neutralization are difficult to interpret, because these cytokines can have autocrine and paracrine regulatory functions and can suppress the expansion of other T_H subsets. For example, while IFN-γ has pleotropic proinflammatory effects, neutralization of IFN-γ and the use of donor T cells that cannot produce IFN-γ exacerbated GVHD. These results suggest that IFN-γ actually has a complex dual role to promote and control GVHD in mice [27]. The presence of eosinophils in duodenal biopsies from patients with GVHD supports the involvement of type 2 cells in the pathogenesis of the disease. In one study, GVHD was more severe in the absence of IL-17a, coincident with a larger IFN-γ response, suggesting that the former suppresses the latter. Another study, however, showed little difference in GVHD recipients of IL-17a-deficient T cells compared with wild-type T cells [119]. The overall results in different systems indicate that T_H1, T_H2, and T_H17 cells can all cause GVHD, although clinical manifestations and the histopathologic patterns may differ and in the absence of one or another cytokine.

Cell-mediated cytotoxic mechanisms clearly contribute to the pathogenesis of GVHD. In an MHC-matched, mHA-mismatched model, expression of MHC class I molecules by non-hematopoietic target tissues was required for GVHD mediated by $CD8^+$ T cells. In contrast, expression of MHC class II molecules by non-hematopoietic target tissues was not required for GVHD mediated by $CD4^+$ T cells. Substantial effort has been devoted to understanding cytolytic mechanisms, mostly in studies with gene-deficient T cells. GVHD is less severe when induced by perforin-deficient T cells compared with wild-type T cells. In a model of GVHD caused by mHAs, FasL-deficient donor T cells caused cachexia but did not cause B-lymphoid hypoplasia or inflammatory lesions in the skin or liver. These results are difficult to interpret, because both perforin and Fas have a role in regulating T-cell responses. The severity of hepatic GVHD was reduced in Fas-deficient recipients, but the severity of GVHD in other organs was increased. Neutralization of FasL prevented hepatic lesions in wild-type recipients but had no effect on intestinal GVHD, whereas neutralization of TNF-α improved intestinal GVHD but had no effect on hepatic GVHD. Neutralization of both FasL and TNF-α prevented GVHD in all organs. Taken together, these results indicate that multiple cytopathic and inflammatory mechanisms are involved in both the afferent and efferent pathways leading to GVHD.

Under certain conditions, activated donor NK cells can reduce the severity of GVHD [30,120]. Mechanisms proposed to explain this effect include production of TGF-β or IL-4 by donor NK cells or rapid elimination of recipient DCs or alloreactive T cells by donor NK cells after the transplant. Donor $CD25^+CD4^+$ Treg cells can also reduce the severity of GVHD in mice. GVHD can be ameliorated by adding large numbers of Treg cells to the graft and is exacerbated by removal of these cells from the graft. The ability of Treg cells to prevent GVHD is partly mediated by their ability to produce IL-10. Results of preliminary clinical trials suggest that Treg cells can diminish GVHD in humans [121,122]. More extensive testing of Treg cells will require the development of better methods for isolating large numbers of these cells or expanding them in culture.

Clinical studies have shown that the risk of acute GVHD depends on the degree of genetic disparity between the recipient and donor. The risk of GVHD is greater with unrelated donors than with related donors, mostly because of unavoidable MHC disparity. The risk of GVHD is higher with multiple disparities than with a single disparity. The type of post-transplant immunosuppression and compliance with the prophylactic regimen influence the risk of GVHD. The most effective regimens currently in widespread use include an antimetabolite such as methotrexate or mycophenolate mofetil in combination with a calcineurin inhibitor (cyclosporine or tacrolimus) or sirolimus (see Chapter 81). Multi-drug regimens are more effective than single-drug regimens. Acute GVHD can be prevented by removing mature T cells from the donor marrow (see Chapter 82). The benefit brought about by a reduced risk of GVHD, however, can be offset by increased risks of graft failure and recurrent leukemia, and by delayed immune reconstitution (see below).

Research studies are attempting to determine whether the donor cells that cause GVHD can be distinguished from those needed to prevent rejection, eliminate malignant progenitors, or initiate immune reconstitution. In the past, many clinical trials have employed methods aimed at global T-cell depletion, even though GVHD is initiated by the relatively small subset of donor cells that recognize recipient histocompatibility antigens. In the future, it may be possible to prevent GVHD by specific depletion of donor T cells that recognize recipient alloantigens, by interference with positive costimulatory signals needed for optimal activation of T cells, by interference with mechanisms involved in the migration of T cells in vivo [123], by administration of agents that increase activation-induced apoptosis in donor T cells that recognize recipient alloantigens, by infusion of Treg cells [121,122,124,125], or by treatment with agents that facilitate expansion of Treg cells in vivo [126]. Possible interference with GVLEs is a concern with all of these approaches. Alternatively, the severity of GVHD might be decreased with the use of agents that protect gastrointestinal integrity [127,128] or decrease intestinal inflammation [129].

Chronic GVHD

The biologic mechanisms leading to chronic GVHD are not as well understood as those leading to acute GVHD [100,130,131]. Although acute GVHD has been recognized as a risk factor for chronic GVHD, evidence suggests that chronic GVHD is not simply the end stage of acute GVHD. Not all cases of acute GVHD evolve into chronic GVHD, and chronic GVHD can develop in the absence of any prior overt acute GVHD. Chronic GVHD is characterized by distinctive clinical and pathologic abnormalities that are not associated with acute GVHD. In the skin, the initial phase of chronic GVHD is characterized by an intense mononuclear inflammatory infiltrate with destructive changes at the dermal–epidermal junction, accompanied by irregular acanthosis, hyperkeratosis, or atrophy. Evolution of the disease is characterized by increasing dermal fibrosis, ultimately resulting in dermal sclerosis (see Chapter 26). Other pathognomonic hallmarks of chronic GVHD include destruction of tubuloalveolar glands and ducts in the skin, salivary glands, and lacrimal glands.

Several hypotheses have been invoked to explain the pathogenesis of chronic GVHD in humans, based on clinical and experimental observations, although no single animal model encompasses all features of chronic GVHD observed in humans. T cells in the graft clearly contribute to the disease, although the target antigens that provoke chronic GVHD might differ from those that provoke acute GVHD. Fibrotic characteristics suggest that chronic antigen stimulation could play a role. Sclerotic manifestations of chronic GVHD may be caused by the activity of profibrotic receptor tyrosine kinases such as fibroblast growth factor receptor and platelet-derived growth factor receptor (PDGFR). For example, cutaneous sclerosis has been associated with the presence of agonistic autoantibodies against PDGFR and, in some cases, sclerotic manifestations have improved after treatment with tyrosine kinase inhibitors. The causal relationship between the presence of these antibodies and the development of sclerotic manifestations remains controversial, and it is possible that the improvement observed in some patients after treatment with tyrosine kinase inhibitors occurred through mechanisms unrelated to agonistic autoantibodies. In humans, the use of growth factor-mobilized blood cells is associated with an increased risk of chronic GVHD compared with marrow, but experimental studies with mice have indicated that T cells do not account for this effect. Phase II studies demonstrating clinical improvement in manifestations of chronic GVHD in some patients after treatment with B-cell-specific monoclonal antibodies have suggested a role for B cells in the pathogenesis of the disease. Excessive production of TGF-β or other profibrotic cytokines could contribute to the development of fibrosis. Thymic damage caused by TBI, acute GVHD, or immunosuppressive medications could lead to failure of negative selection, allowing the production of donor-derived T cells that recognize recipient-specific alloantigens or antigens shared with the donor [132]. Chronic GVHD could result from inadequate production or function of natural or induced Treg after HCT [133,134]. Taken together, these results suggest that multiple pathways involving T cells, B cells, non-lymphoid cells, and Treg cells can lead to manifestations of the clinical syndrome recognized as chronic GVHD.

Graft-versus-leukemia effects

The therapeutic advantage of allogeneic HCT results not only from the ability to deliver more intensive chemotherapy and radiotherapy, but also from antineoplastic effects mediated by the graft (see Chapter 16). Experimental evidence for this GVLE was reported years before the first clinical transplants. Clinical evidence for GVLEs came initially from retrospective observations that leukemic relapse occurred less frequently in patients who developed GVHD than in those who did not. Donor T cells clearly are major mediators of GVLEs. Removal of T cells in the donor marrow has been associated with an increased risk of relapse in addition to a reduction in GVHD. The risk of relapse after T-cell-depleted marrow transplantation for acute leukemia is comparable to the risk in patients who do not develop GVHD after transplantation with unmodified marrow. Experimental animal systems also show unequivocally that alloreactive donor T cells mediate GVLEs.

In patients with acute leukemia, GVLEs tracks closely with GVHD. In contrast, patients with chronic phase (CP) CML who received T-cell-depleted grafts had a higher risk of relapse than those who received T-cell-replete grafts but did not develop GVHD. These results suggest that in patients with CP CML, alloreactive T-cell responses of small magnitude may be sufficient for GVLEs while remaining insufficient for clinically apparent GVHD. Malignant CP CML stem cells (and their normal counterparts) are thus extremely sensitive to attack by allogeneic T cells.

The mechanisms whereby alloreactive T cells can mediate GVLEs have been well studied in murine models [135]. Both CD4- and CD8-mediated GVLEs require recognition of recipient peptide–MHC complexes by donor TCRs [104]. T cells must also make adhesive interactions with ICAM-1 on leukemia cells. The key T-cell effector molecules have varied with the leukemia model used and with the strain pairing. Essential roles for perforin, FasL and TRAIL have been reported in experiments with gene-deficient T cells, but the results of these experiments can be difficult to interpret, since deficiency of these genes in donor T cells can have effects that extend beyond cytotoxic activity [82]. In contrast, experiments with gene-deficient leukemias induced by the retrovirus-mediated expression of oncogenic translocations showed no essential role for Fas, TRAIL-R, TNF receptors, or perforin, indicating that the T-cell effector mechanisms responsible for GVLEs were highly redundant.

NK cells can also mediate GVLEs [83]. A protective effect against AML but not ALL relapse was first observed in HLA-haploidentical HCT with profound T-cell depletion, high CD34 doses, and no calcineurin-based immunosuppression in donor–recipient pairs where the HLA class I types of the donor and recipient predicted for the presence of donor NK cells that lacked an appropriate inhibitory

HLA class I molecule in the recipient [136]. Importantly, alloreactive NK cells do not induce GVHD. Recent work indicated that NK cells can protect against AML relapse in recipients of T-cell-replete grafts from HLA-mismatched unrelated donors [137]. In this study, GVLEs were associated with expression of the activating receptor KIR2DS1 by donor NK cells, but the effect was not observed with donors with strong expression of MHC class I ligands that bind the activating receptor, since this condition induces hyporesponsiveness in developing NK cells that express this specific receptor. Finally, the effect was observed only when recipient cells expressed at least one MHC class I ligand that binds to the activating receptor.

Efforts to gain a therapeutic advantage from interventions designed to increase GVLEs have had mixed success. Among patients with high-risk malignancies, the administration of non-irradiated peripheral blood buffy coat cells from the marrow donor during the first 4 days after transplantation caused an unacceptably high risk of GVHD and transplant-related mortality. Among patients who have recurrent malignancy after transplantation, remissions can occasionally be induced simply by withdrawing immunosuppressive medications. In patients who do not have GVHD, remissions can be induced by infusion of donor lymphocytes (see Chapters 69 and 70). Such remissions occur in approximately 70–80% of patients with CP CML. Remissions occur less often in patients with CML in blast crisis, myeloma, myelodysplasia, and acute myeloid leukemia and much less frequently in patients with acute lymphoblastic leukemia. Donor lymphocyte infusions can cause acute or chronic GVHD and transient marrow aplasia, depending on the number of T cells administered and the degree of HLA mismatching between the recipient and donor.

From a clinical standpoint, a central question is whether GVLEs can be separated from GVHD [138,139]. The separation of T-cell-mediated GVLEs from GVHD could be achieved by using donor T cells that recognize MHC class I-restricted mHAs expressed only on hematopoietic cells and malignant cells in the recipient [140]. Alternatively, T cells could be altered in a way that disables functions that contribute to GVHD but are not required for GVLEs. Finally, T cells could be altered in a way that restricts their ability to migrate to GVHD target tissues, such as the bowel, where malignant cells are less likely to reside. Such strategies have been tested successfully in animal models. Donor NK cells might be especially well suited for mediating GVLEs without GVHD, since they do not cause GVHD.

Development of tolerance

Tolerance after HCT is defined functionally as the presence of immune reactivity without rejection or overt GVHD in the absence of immunosuppressive medications [141] (see Chapter 12). At any given time, immune reactivity potentially involves three main populations of T cells in the recipient: residual recipient T cells, progeny of mature T cells contained in the allograft, and donor-derived T cells that mature from donor progenitor cells in the thymus. Alloreactive residual recipient T cells and progeny of mature T cells in the graft can be controlled by several mechanisms. Under normal physiologic conditions, active suppression is required for peripheral tolerance, since autoimmunity develops in the absence of Treg cells, and the same applies after HCT. Consistent with this hypothesis, donor-derived T helper and T cytotoxic cells that recognize recipient alloantigens can be detected by in vitro assays in all patients after allogeneic HCT regardless of whether clinically evident GVHD has occurred. As discussed above, reconstitution of Treg cells may have an important role in preventing chronic GVHD. Other mechanisms that potentially control alloreactive residual recipient T cells and progeny of mature T cells in the graft include clonal deletion or induction of anergy or exhaustion through chronic antigen stimulation [142–146].

In the thymus, developing T cells originating from donor-derived progenitors are negatively selected by non-hematopoietic thymic components that present recipient antigens through both direct and indirect mechanisms, and by donor-derived DCs that present donor antigens through direct mechanisms and present recipient antigens through indirect mechanisms [147]. Some evidence has suggested that central tolerance can be impaired by GVHD, either because of damage to non-hematopoietic thymic components or because of functional abnormalities in donor-derived DCs. These results raise the possibility that autoimmune responses against epitopes other than mHAs could contribute to late GVHD in humans.

Immune reconstitution

Pathways of T-cell reconstitution

After HCT, all patients develop profound immunodeficiency caused by the preparative regimen, the effects of donor T cells, and the administration of immunosuppressive medications. Reconstitution with donor cells corrects this immunodeficiency (see Chapter 15). Reconstitution of innate immunity with myeloid-derived cells, NK cells, and natural IFN-α/β-producing cells occurs within the first month after transplantation, and reconstitution of adaptive immunity follows later. Risk factors for delayed reconstitution of adaptive immunity include the use of cord blood cells, unrelated donors or grafts containing low numbers of CD34 cells or T cells, older age of the recipient or donor, the occurrence of acute or chronic GVHD, and high-dose glucocorticoid treatment.

Reconstitution of T cells can occur both through thymus-independent expansion of the mature T-cell population in the graft and through maturation of marrow-derived cells in the recipient thymus [148]. Clinical and experimental studies have indicated that the initial reconstitution of T cells after transplantation occurs primarily through proliferation of mature donor T cells in the graft, and the contribution of new T cells from the thymus becomes apparent later. Memory T cells transferred with the graft contribute immediate protective effects, whereas naïve T cells transferred with the graft and new T cells produced through the thymus after HCT confer protection only after priming by infection or immunization. Production of new T cells in the thymus persists throughout life but declines gradually with age, and this decline is at least partly intrinsic to the thymus and not the hematopoietic system. Irradiation, medications used for immunosuppression before and after HCT, and GVHD impair recovery of thymic function after the transplant, with more profound effects in adults than in children. The thymic pathway of T-cell reconstitution is more important for recovery of CD4 cells than for CD8 cells. For these reasons, the balance between contributions from the thymus-independent and thymus-dependent pathways of T-cell reconstitution differs between $CD4^+$ and $CD8^+$ T cells and depends on the age of the patient, the number of T cells in the graft, and the time interval from transplant.

Thymic production of T cells in humans can be assessed by an increase in the volume of the thymus by imaging studies, an increase in the percentage or number of cells with T-cell receptor excision circles (TRECs), and an increase in the percentage or number of cells that express the $CD45RA^+$ $CD30^+$ $CD45RO^-$ phenotype characteristic of recent thymic emigrants. TRECs are formed during the process of *TCR-A* and *-B* gene rearrangement in T cells during development in the thymus. Since TREC DNA is not copied during cell division, the percentage of TREC-containing cells decreases as recent thymic emigrants proliferate. For this reason, the most informative measurements of thymic output require assessment of both TREC content and T-cell proliferation. In lymphopenic mice, naïve T cells emerging from the thymus proliferate because of homeostatic stimulation and convert from a naïve phenotype to a "pseudomemory" phenotype in the absence of specific antigen stimulation. This process is driven by insufficiency of the peripheral T-cell repertoire. T cells that have recently emigrated from the thymus proliferate and convert to a pseudomemory phenotype unless the peripheral repertoire already contains T cells with the same TCR specificity. The presence of naïve T cells in the periphery therefore indicates both thymic output and sufficiency for at least some specificities in the T-cell repertoire.

The time for restoration varies for different components and functions of the immune system. In recipients transplanted with unmodified marrow from an HLA-identical sibling, proliferative responses after in vitro stimulation of T cells with mitogen begin to reach the normal range after approximately 4–6 months, the number of peripheral blood CD4 cells begins to reach the normal range after 7–9 months, and production of immunoglobulin G by in vitro stimulated B cells recovers after 7–9 months. Recovery of immune responses is delayed by several months when T-cell-depleted marrow is used for transplantation, and recovery of CD4 cells is accelerated when hematopoietic growth factor-mobilized stem cells are used for transplantation. Long-term reconstitution of immunity against certain pathogens probably represents the acquisition of new memory cells generated by exposure to antigens after the transplant.

During the first 3 months after HCT, selective proliferation among different T cells in the thymus-independent pathway of reconstitution causes severe skewing in the distribution of TCRs among repopulating T cells. During this time, the spectrum of *TCR* gene rearrangements remains abnormally limited and unstable. Changes in the T-cell repertoire during this period most likely result from alloantigen-driven proliferation, especially in patients with GVHD.

Throughout the first 3 years after the transplant, the progeny of mature T cells in the graft are gradually diluted by T cells that have originated through maturation of marrow cells in the thymus. With this replacement, the spectrum of *TCR* gene rearrangements gradually becomes normal. The rate at which the spectrum of *TCR* gene rearrangements returns to normal depends on the number of mature T cells in the graft and the level of thymic function. Thymus-dependent replacement of cells that originated from the thymus-independent pathway would be expected to occur more slowly with grafts that contain a large number of mature T cells and more rapidly with grafts that contain small numbers of mature T cells. Abnormalities in the spectrum of *TCR* gene rearrangements can persist for more than 3 years in patients with severely impaired thymic function. For reasons that are not yet clear, the spectrum of *TCR* gene rearrangements also remains abnormal in patients with persistent mixed chimerism, even in the absence of GVHD. The diversity of immunoglobulin gene rearrangements in B cells is also reduced after HCT.

Effects of GVHD on immune reconstitution

GVHD impairs T-cell immune reconstitution through at least several distinct mechanisms. GVHD causes injury to thymic epithelium, thereby reducing T-cell reconstitution and diversification of the TCR repertoire through the thymus-dependent pathway [149]. GVHD decreases the total number of T cells that can be accommodated within the periphery, perhaps by causing microenvironmental abnormalities that reduce the number of functional peripheral T-cell niches. Stimulation by recipient alloantigen can cause activation-induced apoptosis in a large fraction of donor T cells that recognize recipient alloantigens, and during GVHD, donor T cells that do not recognize recipient alloantigens are induced to express Fas and become susceptible to fratricidal or bystander apoptosis caused by donor T cells that express FasL. GVHD also impairs the function of APCs, particularly for presentation of antigens to $CD4^+$ T cells [150]. Both acute and chronic GVHD block B lymphopoiesis. Patients with chronic GVHD do not develop immunocompetence until chronic GVHD resolves and until withdrawal of immunosuppressive medications has started.

Opportunistic infections as an indicator of impaired immune reconstitution

Opportunistic infections are a key clinical indicator of immunodeficiency after HCT. Pathogens involved in opportunistic infections prominently include Epstein–Barr virus (EBV) (see Chapter 90), cytomegalovirus (CMV) (see Chapter 87), adenovirus and BK virus (see Chapter 93), HHV6 (see Chapter 92), and fungal organisms (see Chapter 86). The development of lymphoproliferative disorders caused by EBV infection is a particularly striking example of opportunistic infection associated with immunodeficiency after HCT [151]. The risk of this often-fatal complication is increased in patients who receive T-cell-depleted grafts and in patients treated with agents that deplete T cells after HCT, indicating that transfer and persistence of pathogen-specific immunity by memory T cells from the donor have an important role in controlling EBV infection. Risk factors for CMV, fungal, and adenovirus infection are very similar. Prolonged lymphopenia represents a common thread among these risk factors. In particular, CD4 lymphopenia has been strongly correlated with the risk of opportunistic infections after HCT. In addition, more subtle abnormalities of T-cell function are likely to increase the risk of opportunistic infections. Examples include qualitative defects in T-cell signal transduction and reduced production of TNF-α by activated CMV-specific CD8 cells.

Approaches for enhancement of immune reconstitution

In certain conditions, EBV-specific immunity can be reconstituted and regression of EBV-associated lymphoproliferative disorders can be induced by infusion of a relatively small number of donor lymphocytes. Alternatively, immune responses against specific pathogens can be reconstituted by infusion of antigen-specific T-cell lines or T-cell clones (see Chapters 15 and 68). Immune reconstitution might also be accelerated through a variety of other strategies. In mice, administration of keratinocyte growth factor has been shown to protect thymic epithelium from the effects of irradiation and GVHD, thereby improving immune reconstitution through the thymus-dependent pathway after the transplant [152]. Thymic epithelium is a source of IL-7, a growth factor involved in production of T cells and maintenance of T-cell homeostasis in the periphery. Exogenous administration of this cytokine does not reverse the effects of GVHD on thymic stromal function but can enhance T-cell production through direct effects on T cells as they develop in the thymus [153]. Exogenous administration of IL-7 also stimulates proliferation of mature T cells, protects T cells from apoptosis, and enhances T-cell function. Although exogenous administration of IL-7 exacerbated GVHD after HCT in non-irradiated mice, this effect was not observed in irradiated mice in which endogenous levels of IL-7 are already increased because of lymphopenia. Expression of the IL-7 receptor α chain is reduced in donor T cells that have proliferated in response to recipient alloantigens but not in other T cells. For this reason, IL-7 has little effect on T cells that recognize recipient alloantigens but stimulates proliferation of other T cells that may be important for immune reconstitution. Effects similar to those observed with exogenous administration of IL-7 also occur with exogenous administration of IL-15 after HCT. Under some conditions, however, exogenous administration of IL-15 exacerbates GVHD in irradiated recipients. Other potential approaches for enhancing immune reconstitution after HCT include androgen blockade, administration of flt3 ligand or IL-22 [154], and administration of synthetic oligodeoxynucleotides containing unmethylated cytosine–guanine motifs that can expand naïve and memory populations by preventing T-cell death.

In most recipients without chronic GVHD, immunologic function has recovered sufficiently to allow responses after administration of diphtheria, pertussis, and tetanus vaccine and pneumococcal vaccine at 1 year after HCT (see Chapter 106). To some extent, antigen-experienced memory T cells transferred from the donor contribute to this immune reconstitution, and responses to polysaccharide–protein conjugate vaccines in the recipient after the transplant can be enhanced by vaccination of the donor before the transplant. Administration of live viral vaccines, such as measles, mumps, rubella, and oral polio, is deferred until at least 2 years after transplantation, even in healthy recipients, as a precaution to avoid inadvertent infection with these attenuated strains. These vaccines should not be given to patients with chronic GVHD or to anyone taking immunosuppressive medications.

Summary and conclusions

Although this overview of the immunology of HCT has focused on the individual outcomes of engraftment, GVHD, control of malignancy, tolerance, and immune reconstitution, these remain highly interconnected as different aspects of a single overall process. For this reason, the evaluation of interventions designed to influence one particular immunologic outcome of HCT will require equivalent scrutiny of other immunologic outcomes. Historically, clinical HCT has evolved from the biomedical knowledge and understanding gained from animal studies. Murine models have the advantages of well-defined immunogenetics and a wealth of reagents and methods for dissecting the cellular and humoral mechanisms involved in HCT immunobiology, whereas canine and non-human-primate models more closely mimic the immunologic and medical challenges of HCT in a large outbred species. The wide range of experimental manipulations afforded by animal models has allowed rapid progress in elucidating principles that improve the biomedical understanding of HCT immunology in all of its interconnected complexity. The constraints of any given experimental model and the differences between species [155–157] must be carefully considered when results are interpreted and when conclusions are translated for clinical application.

CHAPTER 10
Histocompatibility

Effie W. Petersdorf
Fred Hutchison Cancer Research Center and University of Washington, Seattle; Seattle Cancer Care Alliance, Seattle, WA, USA

Introduction

The human major histocompatibility complex (MHC) is a 7.6-megabase (Mb) region on the short arm of chromosome 6 that contains more than 300 genes, approximately 20–30% of which have immune-related function [1,2] (Figure 10.1). These functions include antigen processing and presentation (the classical *HLA-A*, *B*, *C*, *DM*, *DO*, *DP*, *DQ*, and *DR* genes; *PRSS16*; *PSMB*; *AP*; and *UBD*), inflammation (*ABCF1*, *AIF1*, *DAXX*, *IER3*, *LST1*, *LTA*, *LTB*, *NCR3*, and *TNF*), leukocyte maturation (*DDAH2* and *LY6G*), the complement cascade (*BF*, *C2*, *C4A*, and *C4B*), maternal–fetal immunology (the non-classical class I *HLA-E, F*, and *G* genes), stress response (*MICA*/*MICB*), immune regulation (*NFKB*, *RXRB*, and *FKBPL*), and the immunoglobulin superfamily (*AGER*, *BTN*, *C6orf25*, and *MOG*).

HLA antigens are expressed on virtually all nucleated cells, and this ubiquitous expression contributes to their fundamental role in the acceptance and rejection of transplanted tissues. Most individuals are heterozygous for two different parentally derived alleles at each HLA locus. For a given HLA locus, the antigens encoded by the two HLA alleles are codominantly expressed, and a heterozygous individual will therefore possess two different antigens at that locus. The extensive polymorphism of HLA genes, coupled with their tendency to be strongly linked to one another, has important implications in donor–recipient histocompatibility matching for hematopoietic cell transplantation (HCT).

Evidence for an MHC in humans was first recognized in the early 1950s following observations that sera from patients with febrile transfusion reactions could cause the agglutination of leukocytes from their transfusion donors, in addition to other individuals [3]. Subsequent studies showed that leukocyte antibodies could also be found in the sera of multiparous women. The term "HLA" was derived by combining the human-1 (*HU-1*) and leukocyte antigen (*LA*) designations used by Dausset and Payne, respectively, to describe the newly discovered leukocyte antigen system [3–7] (Table 10.1). Since 1964, a series of 16 collaborative International Histocompatibility Workshops has greatly extended our knowledge of the HLA system and contributed to the standardization of typing methods and nomenclature [8–21] (Table 10.2).

HLA antigens are inherited in classical Mendelian fashion (Figure 10.2). During an immune response, cells of the immune system interact through recognition of cell surface molecules encoded by genes of the human MHC. T cells recognize foreign antigens presented as peptide fragments in association with MHC molecules. Before T cells can recognize an antigen, the antigen must be processed by an antigen-presenting cell, bound to a "self" MHC molecule, and transported to the cell surface. Many different peptide antigens can be processed and presented to T cells, including those derived from bacteria, viruses, toxins, and foreign cells and tissues, as well as from autologous tissue and cellular products. Definition of the peptide-binding motifs that characterize HLA molecules provides important information about the role of the HLA system in peptide presentation, immune responsiveness, and disease susceptibility [22–24]. The role of the MHC in antigen presentation helps explain the extensive polymorphism of the MHC at the population level: the greater the polymorphism of the MHC, the larger is the array of foreign peptides that can be presented to the immune system. In this way, MHC genes influence T-cell immune responsiveness by the selection of antigens that can be bound and presented for T-cell recognition. MHC molecules have a major effect in transplantation due to the fundamental role that they play in T-cell activation and initiation of an alloresponse.

With the advent of DNA typing methods, it is now possible to define each class of HLA molecule by its unique sequence [25] (http://www.ebi.ac.uk/imgt/hla). For a given HLA locus, the unique sequence variant is termed the "allele" (e.g., A*02:01), and the alleles expressed by the two parental haplotypes constitute the "genotype" (e.g., HLA-A*02:01, *03:01). HLA "antigens" refer to molecules defined by their reaction with HLA antibodies. The combination of two antigens at a given locus, encoded by the alleles of the two parental chromosomes, is termed the "phenotype" (e.g., HLA-A2, A3). The remarkable diversity among genes of the HLA system has greatly exceeded expectations and reflects the fundamental role that the MHC plays in immune responsiveness and susceptibility and resistance to disease [26]. An appreciation of HLA polymorphism is also central to understanding how histocompatibility antigens function as transplantation determinants through their interaction with T cells (Chapter 9), natural killer (NK) cells and killer-cell immunoglobulin-like receptors (KIRs) (Chapter 11) and by the presentation of minor histocompatibility antigens (Chapter 16).

HLA genes: structure and function

The MHC was first sequenced in 1999 [27,28] (http://www.hapmap.org/; http://www.sanger.ac.uk/HGP/Chr6/).The "central" portion of the MHC measures 4 Mb in length and houses the classical and non-classical HLA genes. The "extended MHC", or xMHC, comprises a total of 7.6 Mb of sequence, extending from the

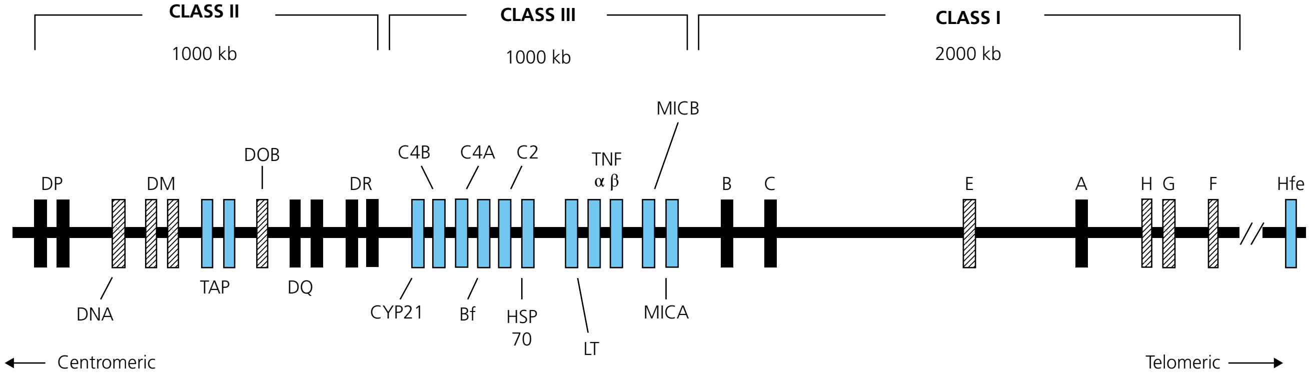

Figure 10.1 The human major histocompatibility complex (MHC) on the short arm of chromosome 6. The class II *HLA-DP*, *-DNA*, *-DM*, *-DOB*, *-DQ*, and *-DR* genes and the class I *HLA-B*, *-C*, *-E*, *-A*, *-H*, *-G*, and *-F* genes are shown in black; those encoding classical transplantation antigens are shown as solid bars, others are cross-hatched. Other HLA region-associated genes are shown in gray: transporter of antigenic peptides (TAP); 21-hydroxylase (CYP21; also termed 21-OH or P450-C21B); complement component C4; properdin factor B of the alternate complement pathway (Bf); complement component C2; heat-shock protein (HSP70); tumor necrosis factor (TNF) complex and lymphotoxin-A (LTA); MICB; MICA; and the hemachromatosis gene (Hfe). The distance from the *HLA-F* gene telomeric to the *Hfe* gene is approximately 4000 kb.

Table 10.1 Definition of commonly used terms in histocompatibility

Term	Definition	Example
Allele code	A system for grouping related alleles together, often defined by the typing technology	HLA-DQB1*02AB signifies HLA-DQB1*02:01 or 02:02
Ancestral haplotypes (AH)	Highly conserved HLA haplotypes derived from a prototype ancestor	HLA-A1B8DR3 (the "8.1" AH)
Direction (vector) of mismatching	Host-versus-graft (HVG): donor alleles not present in the recipient	Recipient: HLA-B7,7 Donor: HLA-B7,8
	Graft-versus-host (GVH): recipient alleles not present in the donor	Recipient: HLA-B7,8 Donor: HLA-B8,8
Epitope	A moiety of a molecule that is immunogenic	Cross-reactive: epitopes shared by two or more HLA antigens Private: epitopes unique to a single antigen
Genotype	An individual's HLA allele sequence(s)	HLA-A*01:01, 02:01
Haploidentical	Relatives who share one chromosome 6 and are variably matched for the non-shared HLA haplotype	Recipient: A1,2; B7,8; DR2,3 Donor: A1,11; B8,44; DR3,4
Haplotype	Markers that travel together on the same chromosome 6 strand	HLA-A1, B8, DR3
Heterozygous	Two different HLA alleles/antigens at the HLA locus	HLA-A*02:01,02:05 (NB: this genotype has the homozygous A2,2 phenotype)
HLA	HU-1 (human-1 antigen) and LA (leukocyte antigen)	Human leukocyte antigens that govern tissue type
HLA allele	An alternative form of a gene; a unique sequence variant	HLA-A*02:01
HLA antigen	The expressed HLA protein for which alloantisera are defined	HLA-A2
HLA class I	The telomeric (further from the centromere) region of the MHC encoding HLA genes	HLA-A, HLA-B, HLA-C ("classical class I genes") HLA-E, F, G; MICA, MICB ("non-classical class I")
HLA class II	The centromeric (closer to the centromere) region of the MHC encoding HLA genes	HLA-DR, HLA-DQ, HLA-DP
HLA class III	The region of the MHC mapping between class I HLA-B and class II HLA-DR	Tumor necrosis factor (TNF); complement pathway genes
Homozygous	Two copies of the same allele/antigen at the HLA locus	HLA-A*01:01,01:01
Identical-by-descent (IBD)	Genotypically identical siblings who have inherited the same maternal and paternal chromosome 6	Patient's and sibling's maternally derived haplotype is A1B8DR3, and paternally derived haplotype is A2B7DR2
Identical-by-state (IBS)	Phenotypically matched unrelated individuals who fortuitously share the same HLA antigens	HLA-A1,2 B7,8 DR2,3 patients and donors
Leukocyte antibody cross-match	An assay that quantifies antibodies in the sera of patients that are directed against the transplant donor's HLA class I and II antigens	
Linkage disequilibrium (LD)	The non-random association of alleles or antigens	HLA-B8 with HLA-DR3 HLA-B8 with HLA-C7 HLA-DR3 with HLA-DQ2
Match grade	The total number of HLA alleles/antigens for which the transplant donor and recipient are matched	Five locus definition (total of 10 possible determinants at HLA-A, -B, -C, -DRB1, -DQB1): 10/10 (fully matched); 9/10 (one HLA mismatched allele or antigen); 8/10 (two mismatched alleles or antigens); etc. Four locus definition (total of 8 possible determinants at HLA-A, -B, -C, -DRB1): 8/8; 7/8; 6/8; etc. Three locus definition (total number of 6 possible determinants at HLA-A, B, DRB1): 6/6; 5/6; 4/6; etc.
Mixed lymphocyte culture (MLC)	A functional assay that measures proliferative responses between two cell populations	
MHC	Major histocompatibility complex	A 7.6-Mb region of chromosome 6p21.3 that encodes the histocompatibility genes important in transplantation

Continued

Table 10.1 *Continued*

Term	Definition	Example
Natural killer immunoglobulin-like receptor (KIR)	A multi-gene system encoded on chromosome 19q13.4 responsible for innate immunity	Inhibitory receptors: KIR2DL3, KIR2DL2, KIR2DL1, KIR3DL1 Activating receptors: KIR2DS1, KIR2DS2, KIR2DS3, KIR2DS4, KIR2DS5, KIR3DS1
Non-inherited maternal antigen (NIMA) match	HLA antigen(s) that is mismatched between a patient and donor, but is shared between the patient and the donor's mother	Patient: HLA-A1,2 Donor: HLA-A1,3 Donor's mother: HLA-A1,2
Phenotype	An individual's HLA proteins	HLA-A1,2
residue	An amino acid of the HLA protein	Residue 116 of class I
Single-nucleotide polymorphism (SNP)	The simplest form of human genetic variation. An SNP is a biallelic nucleotide change	A vs. T A vs. C A vs. G T vs. G etc.
TagSNP	An SNP that is in 100% LD with another SNP(s) so that they serve as proxies for one another	
Typing resolution	Low: broad family of alleles equivalent to antigen	HLA-A2 if defined by serology; A*02 if defined by molecular methods
	Intermediate: group of related alleles within an antigen family equivalent	HLA-A*02:01/02:05
	High: DNA sequence is defined (minimum 4 digits, often 6 digits)	HLA-A*01:01:01

HCT, hematopoietic cell transplantation; HLA, human leukocyte antigen; HTC, homozygous typing cell; MLC, mixed lymphocyte culture; PCR, polymerase chain reaction; RFLP, restriction fragment length polymorphism; SNP, single-nucleotide polymorphism; NGS, next-generation sequencing.

HIST1H2AA gene at the telomeric end, to the *RPL12P1* gene at the centromeric end. HLA genes are clustered in three distinct regions, designated class I, class II, and class III (Figure 10.1). Genes within the class I and class II regions share structural and functional properties and are considered part of the immunoglobulin gene superfamily. Although distinct in sequence and structure, both class I and class II genes encode polypeptides that are critical in controlling T-cell recognition and determining histocompatibility in transplantation.

A characteristic feature of HLA genes is their extreme polymorphism (http://www.ebi.ac.uk/imgt/hla). HLA diversity is a reflection of the primary immunologic function of MHC molecules, which is to bind and present antigenic, and potentially pathogenic, peptides for recognition by antigen-specific T-cell receptors (TCRs). The differing structural properties of HLA class I and class II molecules account for their respective roles in activating different populations of T lymphocytes. Cytotoxic T lymphocytes recognize antigenic peptides presented by HLA class I molecules, whereas helper T lymphocytes recognize antigenic peptides presented by HLA class II molecules. HLA class I and class II molecules are characterized by distinctive α and β polypeptide subunits that combine to form αβ heterodimers of the mature molecule. Class I molecules were originally defined by typing with alloantisera and class II molecules defined by testing in functional assays such as the mixed lymphocyte culture (MLC) reaction [29].

The class I region

Classical HLA genes

At least 17 loci, including several pseudogenes, exist in the HLA class I region (Figure 10.1). Three of these loci, termed class Ia, encode HLA-A, -B, and -C alloantigens important for matching in transplantation. Genes of the *HLA-A*, *-B*, and *-C* loci are highly

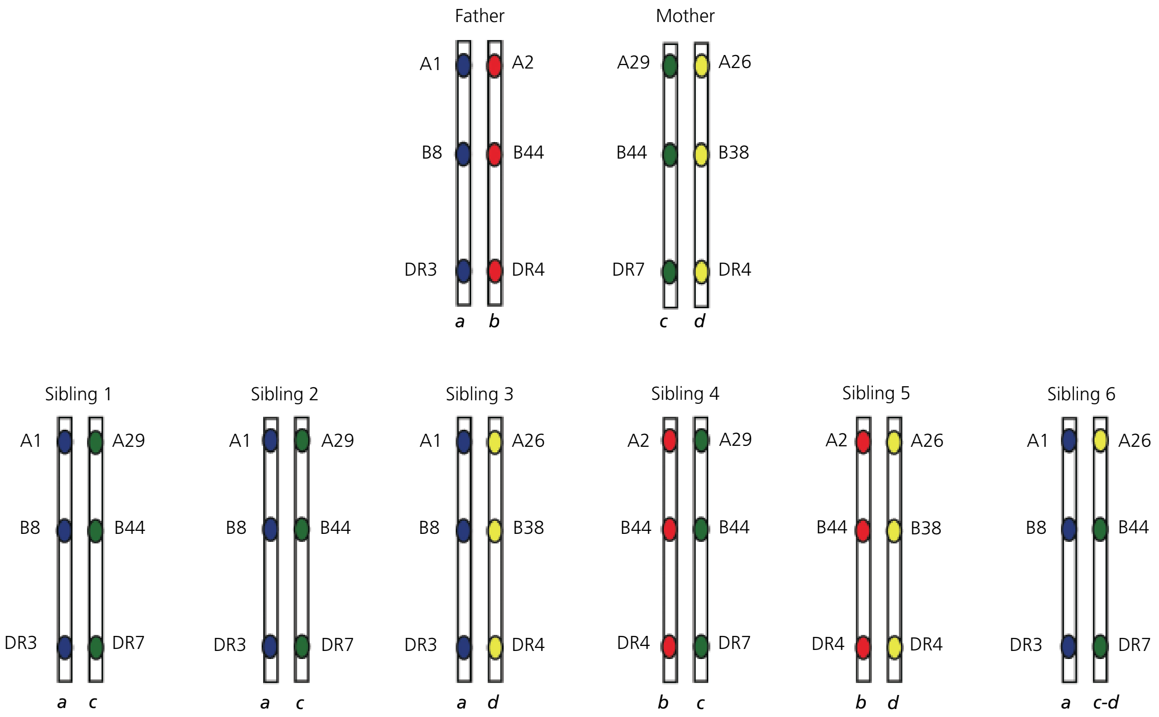

Figure 10.2 A family study. The paternal haplotypes are designated ***a/b*** and the maternal haplotypes ***c/d***. Sibling 1 is the propositus. Compared with sibling 1, sibling 2 is ***a/c*** (HLA genotypically identical), sibling 3 is ***a/d*** (haploidentical), sibling 4 is ***b/c*** (haploidentical), sibling 5 is ***b/d*** (complete mismatch), and sibling 6 is ***a/c–d*** (maternal ***c–d*** recombinant). Siblings 1 and 4 are mismatched at HLA-B in the graft-versus-host (GVH) vector only. Siblings 1 and 6 are mismatched at only HLA-A for both GVH and host-versus-graft vectors; they are matched from HLA-B to DR due to the maternal recombinant haplotype.

polymorphic, with *HLA-B* the most polymorphic locus in the human genome (http//www.ebi.ac.uk/imgt/hla) [25]. *HLA-A*, *-B*, and *-C* genes consist of eight exons and seven intervening introns. Exon 1 is a leader sequence; exons 2, 3, and 4 encode the α1, -2, and -3 domains of the class I molecule, respectively; exon 5 encodes the transmembrane portion, and exons 6, 7, and 8 encode the cytoplasmic tail. The expressed HLA class I molecule consists of a single polymorphic α (heavy) chain approximately 338–341 residues in length that is non-covalently bound at the cell surface to a β_2-microglobulin light chain. The gene for β_2-microglobulin is located outside the HLA complex on chromosome 15. Structurally, class I molecules comprise two α-helical regions overlaying an eight-strand antiparallel β-pleated sheet that together form the functional groove for peptide binding [22]. Nucleotide substitutions within exons 2 and 3 of class I genes are not distributed randomly but are concentrated in discrete hypervariable regions. The corresponding polymorphic sites within the α1 and α2 domains facilitate the binding of peptide fragments for presentation to the TCR [30]. These polymorphic sites determine the allospecificity of the molecule and form the basis for their nomenclature (http://www.ebi.ac.uk/imgt/hla). Polymorphic residues 77–80 of HLA-C molecules and 77–83 of HLA-B molecules (the latter constituting the Bw4 epitope) define the specificity of NK receptor recognition of HLA-C and -B ligands (described below and in Chapter 11).

Non-classical genes

The class I region contains at least three non-classical genes – *HLA-E*, *-F*, and *-G* (class 1b) [31] – and two class I-like genes – *MICA* and *MICB* [32]. *HLA-E*, *-F*, and *-G* loci are very similar to class Ia genes in terms of overall organization and the relationship between exon sequence and function of the encoded molecule. Class Ib genes serve specialized roles in immune responses, and have a prominent role in both adaptive and innate immune pathways. One difference between classical Ia and non-classical Ib molecules is their tissue expression: whereas class Ia molecules are expressed on all nucleated cells and are therefore present in most tissues, class Ib molecules are more restricted in distribution and tend to be tissue specific. Of the three, HLA-E is the most ubiquitously expressed [33]. HLA-G is expressed specifically in placental tissue [34], whereas HLA-F is expressed in the bladder, liver, and placenta and on lymphoblastoid cells [35]. HLA-E and -G molecules serve as ligands for NK cell receptors and thereby regulate NK function [36,37]. HLA-E molecules bind specifically to the conserved leader sequence peptides from class Ia MHC molecules to promote cell surface interactions with the CD94/NKG2 class of NK cell receptors.

MICA and *MICB* genes share amino acid sequence homology with the classical class I proteins but are distinguished from HLA-A, -B, and -C by the lack of association to β_2-microglobulin [38] and the absence of peptide-binding function [32] due to a shallow peptide-binding groove. MIC proteins are expressed in the intestinal epithelium and play a fundamental role as cell stress response genes inducible by heat shock [32]. MICA and MICB products are ligands for the NKG2D-activating receptor involved in NK immunosurveillance and in co-stimulation of T-cell responses [39].

The class II region

The HLA class II region is comprised of nine distinct genes: *DRA*, *DRB1*, *DRB3*, *DRB4*, *DRB5*, *DQA*, *DQB*, *DPA*, and *DPB*. The class II region also encodes *TAP* and *LMP* that play a role in the loading of class I molecules with peptides. Six additional genes or gene fragments are either non-functional pseudogenes or do not encode proteins known to participate in transplant-related immune interactions. Class II genes have been collectively referred to as HLA-D region genes since they were initially described in the mid-1970s after the description of the HLA-A and -B (1965) and -C (1971) loci. Class II genes are divided into five families, designated DR, DQ, DO, DN, and DP, based on their degree of sequence homology and their location within the HLA-D region. Class II HLA-DR, -DQ, and -DP genes, like class I genes, are highly polymorphic (http://www.ebi.ac.uk/imgt/hla) [25].

Class II molecules consist of a single polymorphic (DQ and DP) or non-polymorphic (DR) α chain non-covalently bound to a polymorphic β chain [23]. The β chains of HLA-DR, -DQ, and -DP antigens are encoded by the *DRB*, *DQB*, and *DPB* genes, respectively. Polymorphic HLA-DR β chains are encoded by four distinct DRB genes termed *DRB1*, *DRB3*, *DRB4*, and *DRB5*. HLA-DRB genes are inherited as a genetic unit, or *haplotype*. Within the HLA-DRB region, variable numbers of genes are expressed from one haplotype to another (Figure 10.3). For example, DRB haplotypes that type as DR1 include four genes: a polymorphic *DRB1* gene, a non-polymorphic *DRA* gene, and two pseudogenes. In contrast, DRB haplotypes that type as DR3 include five genes: a polymorphic *DRB1* gene, a non-polymorphic *DRA* gene, a polymorphic *DRB3* gene, and two pseudogenes. Further polymorphism within the HLA-D region can result from *trans* pairing of a polymorphic DQ α chain encoded by one parental chromosome with a polymorphic DQ β chain encoded by the other parental chromosome.

Polymorphic sites within class II molecules are localized in specific regions of the α1 and β1 domains of the α and β chains, respectively, to enable binding of a large array of peptides [30]. The polymorphic α1 and β1 domains also determine the allospecificity of the class II molecule. Antigens encoded by *DRB1* and *DQB* genes are known to be potent stimulators of immune reactions in HCT (Chapter 45).

The class III region

The HLA class III region is located between class II (centromeric boundary) and class I (telomeric boundary) (Figure 10.1). The class III region comprises some 60 genes within approximately 700 kb of DNA, making it the most gene-dense region of the human genome. More than 14% of the sequence within this region is coding, with an average of 8.5 genes per 100 kb of DNA. The class III region genes display positive linkage disequilibrium (LD) with HLA loci, and haplospecific polymorphisms have been described for several common xMHC haplotypes [40]. The class III region has been associated with susceptibility to numerous autoimmune and infectious diseases [26]. Those with proven function include genes encoding the complement components C2, C4, and Bf, tumor necrosis factor, certain transport proteins, and heat shock proteins.

The history of HLA

The description of the first HLA group in 1958 stimulated worldwide interest in the genetic structure and biologic function of the HLA system. It became apparent that the scope of work necessary to elucidate the HLA system would require broad collaboration beyond what would be possible within individual laboratories. This led to the organization of an international group of investigators willing to share reagents and unpublished data, beginning in 1964 (Table 10.2). The first HLA antigens had been defined by individual investigators using their own reagents, antisera, and cell panels, and employing a variety of locally developed laboratory assays. An exchange of reagents was necessary to compare antisera and standardize antigen definition, establish a common nomenclature, and develop standardized testing methods. The International HLA Workshops thus provided a critical mechanism for promoting this collaboration, in addition to creating a forum for new technology and dissemination of reagents worldwide.

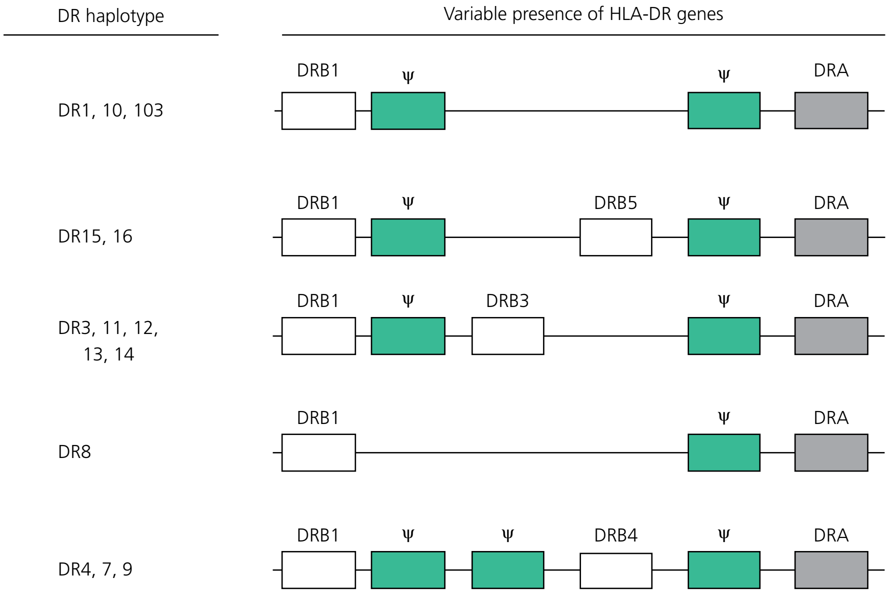

Figure 10.3 Variable expression of *DRB* genes according to HLA haplotype. Clear boxes, *DRB* genes; gray boxes, non-polymorphic *DRA* gene; black boxes, pseudogenes.

The early period: 1964–1972

HLA antigens were discovered in the late 1950s using agglutination assays employing leukoagglutinating [immunoglobulin M (IgM) antibodies. The 1st HLA Workshop (1964) introduced a complement-dependent microdroplet assay that required only microliter amounts of cytotoxic (IgG) antibodies of relatively high specificity and reproducibility. Cytotoxic antisera were carefully selected for HLA specificity and were usually obtained from multiparous women who had been naturally immunized to HLA alloantigens through pregnancy. The in vitro MLC was also studied in the 1st Workshop. The MLC assay involved culturing responder leukocytes, later identified as T lymphocytes, with second-party stimulator cells and measuring the ensuing proliferative response. The magnitude of the response was considered an indication of the disparity between the two cell populations for certain HLA antigens, although the exact nature of these antigens was unknown.

The 3rd HLA Workshop (1967) elucidated that HLA antigens were products of two closely linked loci. A nomenclature committee of geneticists and immunologists was organized to establish standardized nomenclature. The designation of "HL-A" (H standing for the Hu1 system of Dausset, L standing for leukocyte, and A for the first recognized locus within this system) was subsequently adopted [41].

By the 4th HLA Workshop (1970), 11 official HL-A specificities (HL-A1, -A2, -A3, -A5, -A7, -A8, -A9, -A10, -A11, -A12, and -A13) had been defined, with numeric designations being assigned in sequential order of discovery and reporting. At least eight other specificities were given provisional "Workshop" designations (e.g., w27) indicating probable but not conclusive characterization. There was also evidence of a third sublocus within the HL-A system [42]. Following the 5th Workshop (1972), the nomenclature committee confirmed the existence of at least two subloci within the HL-A system and assigned the known antigens to two distinct segregant series, the first, or LA, series, and the second, or FOUR, series. The identity of the locus encoding determinants causing stimulation in the MLC reaction remained to be elucidated.

The middle period: 1975–1984

This period was highlighted by the refinement of serologic methods for class II region determinants, the development of additional cellular assays for the class II region, and a dawning recognition of the enormity of HLA diversity which ultimately ushered in the DNA era of HLA testing. Four International Workshops were held between 1975 and 1984 (Table 10.2). By the 6th Workshop (1975), it was recognized that disparity for HLA-D region antigens led to the lymphocyte activation and proliferation measured in the MLC assay [43]. The 6th Workshop was the first to include the use of homozygous typing cells (HTCs) to study determinants of the newly defined HLA-D locus [44]. Identification of HLA antigens expressed on B cells but not on T cells was termed "Ia-like" or "D region-associated B-cell antigens," and their description paved the way for the future description of the HLA-DR locus. Following the 6th Workshop, the World Health Organization Nomenclature Committee adopted the term "HLA" to reflect the multi-locus nature of the MHC.

Although the direct MLC had been used as a tool for donor selection in HCT since the late 1960s, its utility as a test of histocompatibility was largely restricted to confirming HLA-D region compatibility between HLA-A, -B, -DR serologically matched donors and recipients. Data were ultimately published indicating that the MLC was not consistently predictive of the risk of clinically severe acute graft-versus-host disease (GVHD) [45]. In the late 1980s, DNA-based methods supplanted both the direct MLC and the use of D-region homozygous typing cells for the evaluation of donor–recipient compatibility in HCT. In contrast, the leukocyte antibody cross-match continues to be used as an important indicator of histocompatibility in HCT. Historically, leukocyte antibody cross-matches were performed using a complement-dependent cytotoxicity assay testing recipient serum against donor lymphocytes. More recently, cross-matches have been performed utilizing the highly sensitive and specific flow cytometry. By using fractionated T and B lymphocytes as target cells in the cross-match assay, antibodies directed against both HLA class I and class II antigens can be demonstrated. A positive antidonor result in the complement-dependent cytotoxicity assay, indicative of the presence of donor-directed HLA antibodies in the HCT recipient, is highly predictive of graft failure [46]. Similarly, a positive patient antidonor cross-match by flow cytometry is predictive of graft failure [47].

In the mid-1980s, serologic typing became more refined as large numbers of highly specific HLA antisera were accumulated and tested against diverse panels of target cells. It was soon recognized that operationally monospecific antibodies could detect alloepitopes shared by more than one HLA class I gene product [48]. The term "cross-reactive" was coined to describe antigenic epitopes shared by two or more distinct HLA antigens, "public specificities" to describe epitopes shared by more than one distinct antigen, and "private specificities" to describe epitopes that were unique to a single antigen. The identification of private and public specificities provided a means to cluster serologically cross-reactive antigens into cross-reactive groups (CREGs). In the early unrelated donor transplant experience, CREG-mismatched unrelated donors were considered when matched donors were not available [49]. By the 9th HLA Workshop (1984), more than 124 HLA specificities at the A, B, C, D (MLC-defined), DR, DQ, and DP loci had been defined [50].

The later period: 1987 to the present day

The HLA Workshops provided a unique framework for testing functional assays for alloimmunogenicity. Primary among these was the limiting dilution assay, a modification of the MLC in which patient and donor cells are co-cultured for an initial 3–6-day priming phase, followed by plating at limiting dilution which then generates a readout of patient-versus-donor and/or donor-versus-patient alloimmune reactivity. The frequency of both cytotoxic T-lymphocyte precursor and helper T-lymphocyte precursor cells can be measured [51,52]. The presence of elevated patient antidonor cytotoxic T-lymphocyte precursor and/or helper T-lymphocyte precursor frequencies might signal an increased risk of rejection of the allograft, whereas the presence of elevated donor anti-patient precursor frequencies might signal an increased risk of GVHD. Today, cellular methods have been supplanted by DNA assays, although the former may have some utility in donor screening when several otherwise equally matched donors are available [53].

The discovery of polymerase chain reaction (PCR) technology in the mid-1980s propelled the HLA field into the DNA era. At that time, the development of PCR-based methods was feasible for HLA-DR because of the availability of sequence information at this locus. The 10th Workshop (1987) was the first to introduce DNA-based laboratory methods for tissue typing. Three major technologies emerged and became integrated in both clinical and research applications: sequence-specific primer (SSP) methods [54] (Figures 10.4 and 10.5); sequence-specific oligonucleotide probe (SSOP) hybridization [55,56] (Figures 10.6 and 10.7), and direct

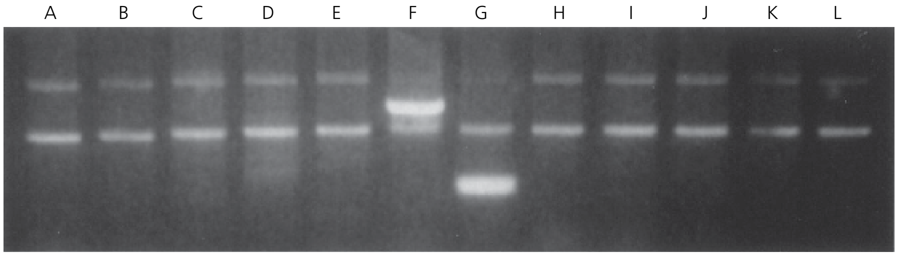

Figure 10.4 Sequence-specific primer (SSP) typing for HLA. In the SSP method, a panel of amplification primers is designed to detect all known polymorphisms encoded by an HLA locus or group of alleles. Polymerase chain reactions (PCRs) are first performed for each of the primer pairs. The PCR products are then electrophoresed on a gel, and the presence or absence of a PCR product of the appropriate size is scored. Assignment of an HLA type is made by examining the pattern of positive and negative PCR reactions. Advantages of the SSP method include its relatively low cost, its technical simplicity, and the speed with which low-resolution typing can be achieved. High-resolution-level typing requires as many primers as there are polymorphisms, and large numbers of PCR reactions are therefore necessary, increasing both assay time and cost. This figure shows the results of a typical SSP assay in which genomic DNA from a single sample was amplified with a panel of HLA-C primer pairs, electrophoresed on an agarose gel, stained with ethidium bromide and visualized with ultraviolet translumination. All primer pair amplicons (lanes A–L) showed amplification of the 796-base pair (bp) fragment from the internal control primers, demonstrating successful PCR conditions in each sample. The sample was typed as C*06 and C*07 by the identification of specific amplification products in lane F (1062 bp fragment specific for C*07:01/07:02/07:03) and lane G (304 bp fragment for C*06).

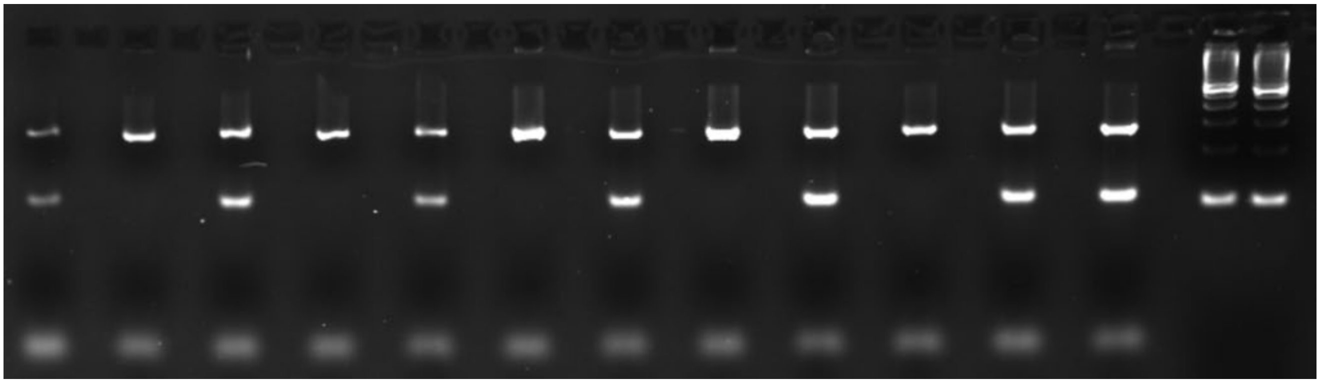

Figure 10.5 Sequence-specific primer (SSP) typing for KIR2DS2 allele typing as described in [87]. Each lane represents a unique DNA sample. An amplified PCR product of 110 bp is represented by the lower band and is indicative of the presence of KIR2DS2 in the sample.

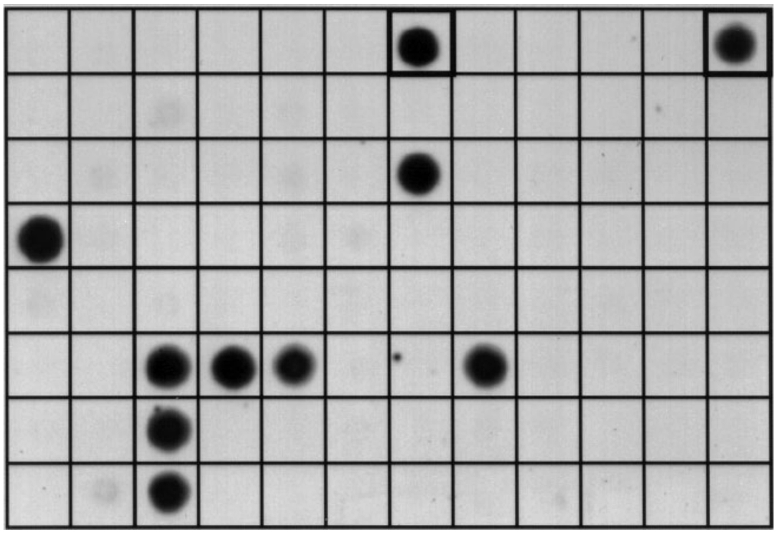

Figure 10.6 Sequence-specific oligonucleotide probe (SSOP) "forward blot" typing. With this method, the HLA gene of interest is amplified by PCR and immobilized on nylon membranes. Oligonucleotide probes labeled with a reporter molecule (either radioactive or non-radioactive) are then allowed to hybridize to the membranes. Probes with sequences complementary to the membrane-bound DNA will hybridize, whereas those with as little as a single nucleotide mismatch will not. The pattern of positive and negative hybridization is used to deduce the HLA type of the target DNA. In this method, only the known polymorphic sites in an HLA gene are probed, and therefore no information is obtained for regions of the gene not defined by the sequence-specific probes. Although novel patterns of probe hybridization may indicate the possible presence of a new allele, alleles with polymorphisms outside the probed regions may escape detection. Since many samples being examined for a given HLA gene can be tested on the same set of membranes, the SSOP method is particularly well suited to high-volume HLA typing. This figure shows the results of SSOP typing of genomic DNAs of 12 known control samples and 82 unknown samples that were amplified with HLA-A locus-specific primers, blotted on a series of nylon membranes and probed with a panel of HLA-A locus probes. Positive hybridization of probes labeled with alkaline phosphatase was detected by chemiluminescence and exposure to X-ray film. In this example, a probe specific to a sequence found only in A*29 and A*43 at codons 62 and 63 of exon 2 showed positive hybridization with two control samples (outlined in bold) and eight of the unknown test samples.

automated sequencing-based typing (SBT) [57,58] (Figure 10.8). As the use of these methods in the research and clinical settings increased, so did the discovery of novel HLA alleles. As a result, the HLA Nomenclature Committee introduced new guidelines for the naming of HLA alleles. The allele was defined by the genetic locus (DRB1) followed by an asterisk separating the locus from the allele name. The first two digits of the allele name correspond to the broadly defined serologic specificity group to which the allele belongs, with the second two digits uniquely identifying the allele. In 1989, official designations were, for the first time, assigned to HLA alleles that had been sequenced. A total of 56 HLA class I and 78 HLA class II alleles were recognized. In 1990, the discovery of "silent" (synonymous) nucleotide substitutions in HLA genes (i.e., those that do not result in changes in amino acid composition of the encoded HLA molecule) required the addition of a fifth (and later sixth) digit to the allele name.

Figure 10.7 Sequence-specific oligonucleotide probe (SSOP) "reverse probe" format typing. In this assay, the sequence-specific probes are immobilized on a solid-phase support. Sample DNA is labeled during PCR amplification and allowed to hybridize to the immobilized panel of probes. As with forward SSOP, HLA alleles are deduced from the pattern of positive and negative probe reactions. In this figure, genomic DNA was amplified with DRB locus-specific biotinylated primers and hybridized to a panel of probes for *DRB1*, *DRB3*, *DRB4*, and *DRB5* sequences immobilized on a nylon membrane strip. The pattern of positive hybridization reactions, detected by color formation, was interpreted with a computerized analysis program. The sample was typed as DRB1*15 or -*16 by the presence of band A, DRB1*04 by bands B and C, DRB4*01 by band D, and DRB5*01:01 or *01:04 by bands E and F.

DNA-based methods were a major theme of the 11th Workshop (1991). This workshop explored the extent of diversity of HLA class II genes and was the first workshop to introduce high-throughput strategies for HLA class II typing. In 1994, the first HLA null allele, DRB4*01012N, was recognized. To accommodate the growing number of polymorphisms within coding and non-coding regions of HLA genes, additional digits were added to the nomenclature system. Beginning in 2002, the expansion of HLA allele designations to eight digits provided greater flexibility for cataloguing variation. Many of the alleles defined by DNA-based typing methods do not have a serologically defined equivalent, placing a further requirement for flexibility and adaptability on the HLA nomenclature system. Application of PCR-based methods in the mid-1990s carried through to the 12th HLA Workshop (1996), in which methods for characterizing classical class I alleles were a breakthrough for population-based analysis. The 12th Workshop included studies of human diversity, HLA in cancer, transplantation, and disease, in addition to a thorough exploration of newly defined HLA genes, alleles, and haplotypes.

With DNA-based typing technology solidly established in HLA research, the 13th and 14th HLA Workshops focused international collaborative efforts on furthering understanding of the functional significance of the MHC in disease models. The 13th Workshop (2002) launched new research initiatives, including studies of cytokine gene polymorphism, HCT, disease, cancer, reproduction, peptide repertoire, the KIR system, and minor histocompatibility antigens. A major contribution of the 13th Workshop was the

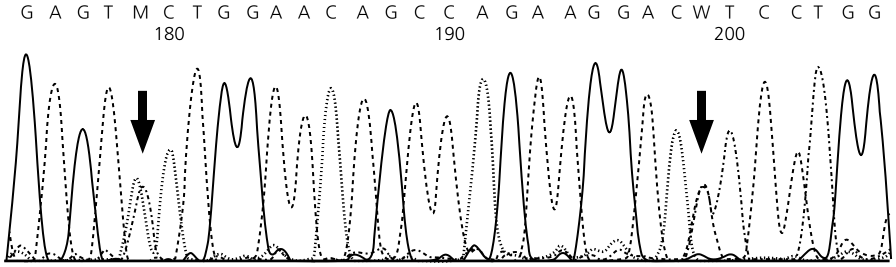

Figure 10.8 Automated fluorescent sequencing-based typing (SBT). The HLA gene is first amplified in a PCR. Cycle sequencing of the PCR product is then performed using primers that are labeled with a fluorescent label (dye primer, usually 5′-primer). Alternatively, the dideoxynucleotides ddATP, ddTTP, ddGTP, and ddCTP can be individually labeled with fluorescent label (dye terminator). In dye primer sequencing, the label is incorporated into the 5′- end of the HLA sequence, whereas in dye terminator sequencing the addition of a labeled dideoxynucleotide at the 3′ end terminates the sequencing reaction. In both approaches, the sequencing reaction is electrophoresed on a polyacrylamide gel using an automated sequencer. The fluorescent signals are captured and interpreted as a sequence of DNA bases by a computer program. Assignment of the HLA allele(s) is performed by comparing the derived sequence with all known sequences for a given gene. This figure shows the partial sequence chromatogram for polymorphic positions 179 and 199 (arrows) of *DRB1* exon 2 (residues 60 and 67) from an HLA-DRB1*08:01,12:01-positive sample. The genomic DNA was sequenced using direct automated dye primer fluorescent chemistry on an Applied Biosystems Model 377 sequencer (ABI, Foster City, CA, USA). The laser-induced fluorescent signal emitted from each sequenced fragment is captured and interpreted by software and identified on the chromatogram above the peak as an A, C, G or T nucleotide base, except at heterozygous positions. Using the International Union of Biochemistry codes, heterozygous position 179 has M, indicating signals from A (DRB1*08:01) and C (DRB1*12:01), whereas the W at position 199 indicates that T (DRB1*08:01) and A (DRB1*12:01) were incorporated.

creation of a public database (*db*MHC) in collaboration with the National Institutes of Health, the National Center for Biotechnology Information, and the National Library of Medicine. By 2008, the number of newly identified alleles mandated a new nomenclature to accommodate the rapid discovery of novel sequences. The WHO Nomenclature Committee for Factors of the HLA System developed a nomenclature that permits unlimited numbers of unique alleles to be individually named, as described below. The most recent 16th International HLA Workshop (2012) focused on the biological implications of MHC diversity in solid organ transplantation and autoimmune disease, and the development of informatics to support data analysis. The International Histocompatibility Working Group in Hematopoietic Cell Transplantation (IHWG in HCT) conducted studies on the role of HLA and KIR genes in unrelated donor transplantation (Chapter 45) [59]. New studies were initiated for cord blood and haploidentical related donor transplantation, paving the way for analysis of MHC region and genome-wide investigation of genes of importance in transplantation.

Nomenclature

As of April 2015, more than 3107 HLA-A, 3887 HLA-B, 2623 HLA-C, 1726 HLA-DRB1, 780 HLA-DQB1, and 520 HLA-DPB1 alleles had been defined (http://www.ebi.ac.uk/imgt/hla) [25]. To accommodate the rapid discovery of sequences, the WHO Nomenclature Committee on Factors of the HLA System established a new nomenclature in 2008 (http://www.ebi.ac.uk/imgt/hla). A hyphen separates the HLA prefix from the gene (HLA-A). Following the gene, an asterisk delimits four kinds of information (in order): the serological equivalent; the unique protein; synonymous substitutions, and non-coding variation affecting expression. Each of these numbers are delimited from one another by a colon (:). For example, HLA-A*02:101:01:02N signifies an HLA-A allele of the A2 family; it has a unique coding sequence named 101, a synonymous change named 01, and is the 02 null (N) allele. The use of colons to separate these four categories permits an unlimited number of novel alleles to be named.

Nomenclature for the KIR genetic loci is analogous to that adopted for HLA and is the responsibility of the HUGO Genome Nomenclature Committee (HGNC) [60]. KIR genes are descriptive of their molecular structure. The name begins with the KIR acronym followed by the number of immunoglobulin-like domains and the letter "D" for "domain". After D, the letter "L" designates molecules with a "long" cytoplasmic tail, whereas "S" is used for "short" cytoplasmic tails, and "P" for "pseudogenes". The name concludes with the number of the gene that encodes the protein with the aforesaid structure. For example, "KIR2DL1" indicates a protein with two domains, a long cytoplasmic tail and is the first protein described. The full description of the KIR genetic system is presented in Chapter 11.

Hallmarks of the MHC: linkage disequilibrium (LD) and haplotypes

If each HLA allele occurred randomly, more than 5.7×10^{31} unique HLA-A, -B, -C, -DRB1, and -DQB1 phenotypes would be possible and the prospects of identifying a matched unrelated donor would be insurmountable. However, the HLA region is characterized by positive LD, in which two or more alleles occur in non-random association and are observed at a higher frequency than would be predicted by chance alone, that is, by the product of their individual allele frequencies. In studies of unrelated individuals where no family study is available, LD is often used as a mathematical prediction of the departure from expectation given the known frequencies of the phenotype or genotype in the population [61].

Strong positive LD between HLA-B and -C and between HLA-DR and -DQ increases the probability that a patient and donor matched for HLA-A, -B, and -DR will also be matched for HLA-C and -DQ. Conversely, mismatching at HLA-B or -DR increases the chance of HLA-C or -DQ mismatching, respectively. HLA-A1, -B8, and -DR3, the most common North American white person haplotype, serves as a good example of how LD may aid in the identification of unrelated donors. Matching for two loci (e.g., A1 and B8) will almost always determine matching for the third (e.g., DR3), fourth (e.g., C7), and fifth (e.g., DQ2) loci. Moreover, an antigen (e.g., HLA-B8) that shows characteristic LD with another antigen is often found to be encoded by a specific and characteristic allele (e.g., HLA-B*08:01). Using the example of the HLA-A1, -C7, -B8, -DR3, and -DQ2 haplotypes, the alleles that encode the phenotypically defined antigens of this group are HLA-A*01:01, -C*07:02, -B*08:01, -DRB1*03:01, and -DQB1*02:01, respectively. The success of identifying suitable unrelated donors is a function of the haplotypic combination of alleles that the recipient has inherited. When patients possess HLA haplotypes with rarer combinations of alleles, it may be feasible to match for some but not all loci. LD phenomena also explain the highly complex patterns of multilocus HLA mismatching among unrelated donors and transplant recipients that have been uncovered in the retyping effort of legacy samples [62,63].

HLA alleles are inherited en bloc as a haplotype on the same strand of DNA. A rigorous identification of haplotypes can only be achieved by ascertainment of segregation of markers in a family study. The family study plays an important early role in planning for an allogeneic transplant. A family study provides the definitive means to validate the patient's genotype and to determine the availability of HLA genotypically identical siblings who might be considered donors. The probability that a patient and sibling will inherit the same two parental haplotypes is 25% ("HLA genotypically identical" or "identical-by-descent") (Figure 10.2). The probability that a patient and sibling have inherited one identical paternal or maternal haplotype and one non-identical (non-shared) haplotype is 50% ("haploidentical"). The probability that a patient and sibling have inherited neither of their parental haplotypes in common is 25%. HLA genotypically identical siblings are identical by descent and therefore share not only the same HLA alleles and antigens, but also all variation linked to the haplotypes. Haploidentical siblings are identical by descent only for the shared haplotype; they are variably mismatched for the non-shared haplotype, depending on fortuitous sharing of maternal and paternal HLA alleles and antigens. In rare situations, a maternal or paternal recombination event gives rise to HLA mismatching between two otherwise matched siblings. Unrelated donors and patients who share the same HLA antigens and alleles are "identical-by-state" because they do not share the same parental haplotypes.

Haplotypes include the known HLA alleles that are physically linked on the same DNA strand in addition to undetected interlocus variation. The terms "ancestral haplotypes" (AHs) and "conserved extended haplotypes" refer to the definition of specific conserved long stretches of DNA sequences thought to be derived from a prototype ancestor [64]. AHs include HLA-B7, -B8, -B13, -B35, -B44, and -B57, observed at high frequency in white populations [40,64]. New ethnically specific haplotypes are generated by the shuffling of interlocus ("frozen") blocks of conserved regions at points of low LD. Recombinational events together with gene conversion, genetic drift, and balancing selection result in haplotypes that share not only the same HLA alleles, but also blocks of highly conserved sequences in strong positive LD with those HLA alleles [40,65–67]. In this way, HLA alleles are markers for untyped genetic variation including novel genes that are potentially important in transplantation (described below). A specific HLA allele may also be found on one or several different haplotype backgrounds [66,68,69]. Although haplotype-specific alleles and blocks have been well characterized for many of the common haplotypes, the extent of block sharing among other less common haplotypes on unrelated chromosomes is unknown.

Intergenic variation within the MHC

The classical HLA genes that currently form the basis of histocompatibility testing in support of allogeneic hematopoietic cell transplantation represent a minority of the total gene content of the human MHC. Mapping the MHC for new genes of importance in transplantation has been facilitated by information on the content and organization of microsatellites and single nucleotide polymorphisms (SNPs) (Chapter 45) [2].

Microsatellites were the earliest form of non-coding variation to be studied in detail within the MHC. Microsatellites are di-, tri-, tetra-, and pentanucleotide repeats and complex repetitions, and have been instrumental in the construction of the second-generation human genome map [70]. Since 1996, over 400 microsatellites have been identified within the central MHC, of which 241 are polymorphic and occur on average one every 16 kb. Although it is not likely that microsatellite markers themselves confer susceptibility to disease, microsatellites can serve as functional coding and regulatory elements. Microsatellites located in the upstream promoter regions of coding sequences may provide enhanced function to expression vectors and binding sites for regulatory proteins, and affect transcription [71].

Microsatellites have been powerful tools for mapping novel transplantation determinants within the MHC [72,73]. In an analysis of 31 markers in 344 HLA-matched unrelated donor–recipient pairs, microsatellites were in strongly positive LD over much of the MHC [73]. Five common White haplotypes (HLA-A1, -B8, -DR3; -A3, -B7, -DR2; -A2, -B44, -DR4; -A29, -B44, -DR7; and -A2, -B7, -DR2) were examined using a new measure called "haplotype-specific heterozygosity," which predicted informative microsatellites. The HLA-A1, -B8, -DR3 and HLA-A3, -B7, -DR2 haplotypes could be predicted with over 90% probability using three microsatellite loci (D6S265/ D6S2787/D6S2894 and D6S510/ D6S2810/D6S2876, respectively). These results demonstrate that microsatellites are informative markers for HLA haplotypes and that sequence variation exists outside the classical HLA loci.

SNPs are the most abundant kind of inherited variation [74]. Over 11 million SNPs have been deposited in the dbSNP public repositories at a density of 1 per 180 base pairs (bp) (http://www.hapmap.org/; http://www.sanger.ac.uk/HGP/Chr6/) [28]. An estimated 4% of these SNPs occur in coding and 96% within non-coding regions of genes [75]. SNPs represent the simplest form of human genetic variation. They represent two different alleles, for example, A versus G, T versus A, C versus T. Since they are very efficient and cost-effective to genotype [76] (Figure 10.9), intense efforts have been made to define the linkage of SNPs in genomic DNA, to specify the organization of SNPs into haplotype blocks, and to identify tagSNPs that could serve as proxies for haplotype blocks. Most often, haplotypes are used as proxies for ungenotyped markers because they may allow the identification of susceptibility markers that might escape detection when tested individually. In this way, the use of haplotypes for disease mapping is especially informative for association studies of complex human diseases wherein the full extent of genetic variability within individuals is unknown [77].

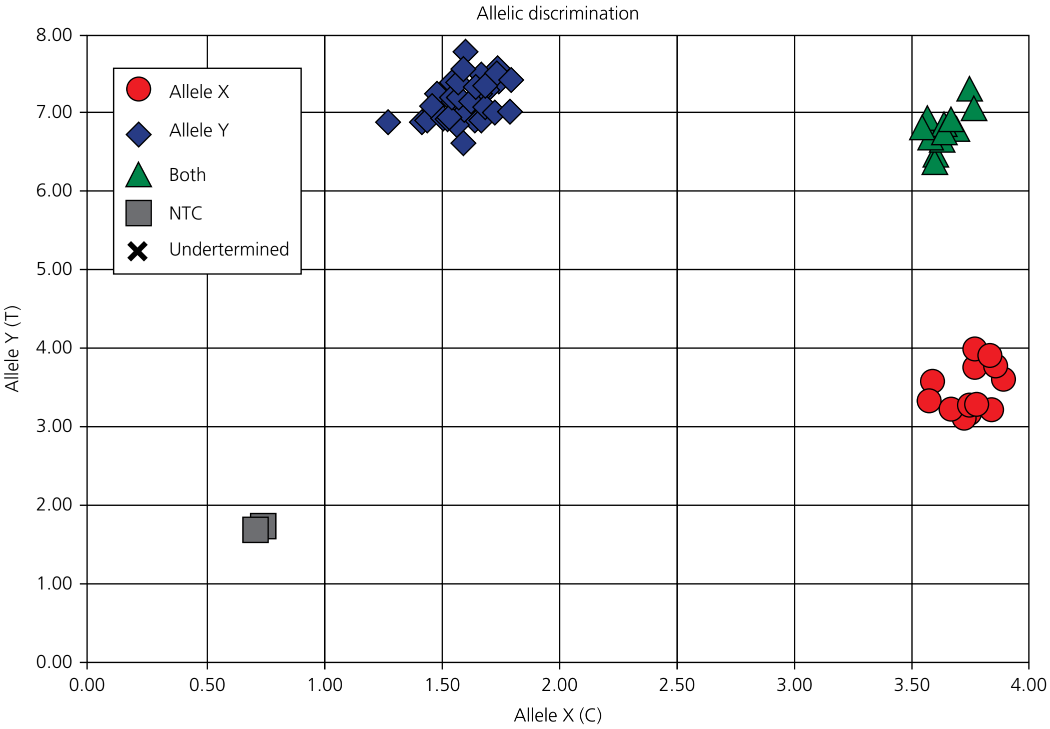

Figure 10.9 SNP genotyping using the TaqMan chemistry [76]. Simple bialleleic SNPs are genotyped as homozygous "allele X" (circles), homozygous "allele Y" (diamonds) or heterozygous (triangles).

The HapMap and 1000 Genomes projects paved the way for the analysis of genome-wide SNPs to study the content and architecture of the human genome, the extent of positive LD, and the organization of variants on haplotypes in ethnically diverse populations. Analysis of SNPs within the MHC reveals striking haplotype organization, with "blocks" of SNPs extending across 40–80 kb. HLA haplotypes have characteristic conservation for SNPs, and HLA haplotypes differ from one another in the size and content of their blocks. Sequencing of eight HLA homozygous cell lines [2] uncovered haplotypic diversity among discrete blocks across the MHC, such that haplotypes defined by their HLA-A, -B, and -DR tissue type exhibit further haplotypic diversity within blocks measuring 20–60 kb in length.

KIR genes and haplotypes

HLA-A, -B and -C serve as ligands for KIR receptors, and hence bridge the innate with the adaptive immune systems. NK cell receptors have inhibitory or activating potential, and it is the balance of these effector functions that results in the NK-cell response to altered or loss of self MHC antigens [78]. Inhibitory NK cell receptors include the KIRs and the immunoglobulin-like transcripts encoded on chromosome 19q13.4. Genetic KIR variation is generated through both allelic and haplotype diversity [60,78]. The inhibitory receptors KIR2DL3, KIR2DL2, and KIR2DL1 recognize epitopes presented by HLA-C antigens, whereas the KIR3DL1 receptor recognizes the HLA-Bw4 expressed by some HLA-B antigens, discussed below. The immunoglobulin-like transcript-1 receptor recognizes HLA-A, -B, -C, -G, -E, and -F as its ligands. A second structurally distinct group of inhibitory receptors consists of CD94 covalently bound to NKG2A, known as the C-type lectin receptors; these genes are encoded on chromosome 12p12–p13 and serve as the receptor for HLA-E.

The inhibitory KIR receptors and their HLA-C and -B ligands are the best studied. The ligand specificity of inhibitory KIR receptors is governed by residues 77 and 80 of HLA-C and by the HLA-Bw4 epitope present on some HLA-B and -A molecules [78]. High-resolution typing of the transplant recipient and donor for HLA-A, -B, and -C genes provides all the information required to determine the presence/absence and heterozygosity/homozygosity of ligands, donor–recipient mismatching for ligands, and specificity for inhibitory KIRs. Based on HLA-C residue 77/80 polymorphism, two groups of HLA-C ligands are distinguished. The Ser77/Asn80 polymorphism is encoded by HLA-C group "C1" molecules (HLA-C1; C3 except C*03:07, *03:10, *03:15; C7 except C*07:07, *07:09; C8; C12 except C*12:05, *12:041/2; C13; C14 except C*14:04; C*15:07; and C16 except C*16:02), and is the ligand for the inhibitory KIR2DL2 and 2DL3 receptors. The Asn77/Lys80 polymorphism is encoded by the HLA-C group "C2" molecules (HLA-C2; C*03:07; C*03:15; C4; C5; C6; C*07:07, *07:09; C*12:05, *12:041/2; C15 except C*15:07; C*16:02; C17; and C18) and is the ligand for the KIR2DL1 receptor. The third ligand group is specified by the presence of the HLA-Bw4 epitope present in B5, B13, B17, B27, B37, B38, B44, B47, B49, B51, B52, B53, B58, B59, B63, B77, B*15:13, B*15:16, B*15:17, B*15:23, and B*15:24 sequences; the Bw4 ligand is recognized by the inhibitory KIR3DL1 receptor.

Two broad groups of KIR haplotype are recognized and are referred to as "group A" and "group B" [60,78]. Group A haplotypes encode primarily inhibitory receptors and the activating KIR2DS4 gene. Group B haplotypes exhibit extensive diversity by encoding more activating genes, including KIR2DS1, KIR2DS2, KIR2DS3, KIR2DS5, and KIR3DS1. Inhibitory KIR receptors have greater affinity for class I ligands than do activating KIR receptors. HLA serves a dominant role in the selection of the peripheral repertoire of NK-cell inhibitory KIRs through its function as a ligand. During normal development, NK cells that express inhibitory KIRs with specificity for self-class I are selectively enriched. Although both inhibitory and activating KIRs are expressed on NK and some T cells, inhibitory KIRs are dominant.

The known ligands for the activating receptors are MHC class I molecules. KIR2DS1 and KIR2DS4 have specificity for HLA-C, CD94/NKG2C for HLA-E, and NKG2D for MHC class I polypeptide-related sequences A and B, and retinoic acid early transcript-1/UL16 binding protein (RAET1/ULBP).

Models for donor inhibitory KIR-mediated killing

Donor NK-cell alloreactivity against host cells can arise in both the HLA-mismatched the HLA-matched settings. As described in Chapters 11 and 44, the sentinel discovery by the Perugia team that recipient target cells are susceptible to lysis via donor NK-cell recognition of HLA ligands has provided a model for understanding the HLA–NK genetic systems [79,80]. In the original observations, graft-versus-host (GVH) vector KIR ligand mismatching occurs when HLA class I ligands are present in the donor but absent in the recipient. In the setting of HLA-mismatched transplantation (haploidentical mismatched related donors and recipients and HLA-mismatched unrelated donors and recipients), recipients may lack the appropriate ligand that is present in the donor due to the HLA mismatch (Table 10.3). The recipient's target cells are susceptible to alloreactive donor NK-cell killing (GVH) because the donor NK cells are not inhibited. The recipient target cells include residual host leukemia or tumor cells. As an example, in the mismatched setting between a donor who has both a C1 (HLA-C8) and a C2 (HLA-C6) epitope and a recipient who has only C1 (HLA-C8, C8 homozygous), donor inhibitory KIRs are not engaged and recipient targets are lysed. With regard to the Bw4 epitope, donor inhibitory KIRs are not inhibited with a Bw4-positive donor and a Bw4-negative recipient. For example, this situation is present in a B44,18-positive donor and a B18,18-positive recipient [donor Bw4 (B44), Bw6 (B18); patient Bw6 (B18), Bw6 (B18)], and also in a B44,52-positive donor and a B18,35-positive recipient [donor Bw4 (44), Bw4 (B52); patient Bw6 (B18), Bw6 (B35)]. High-resolution typing of class I provides the necessary data to test hypotheses related to the clinical importance of ligand mismatching and ligand absence.

Histocompatibility testing of donors for allogeneic transplantation

Typing methods

Because of the broadly reactive nature of HLA antibodies, two or more unique sequences (e.g., HLA-A*02:01 and *02:05) may have the same serologically defined phenotype (e.g., HLA-A2). An increasing number of class I and class II alleles have been discovered with the use of DNA-based typing methods and have not been phenotyped by serologic methods. To bridge the transition in nomenclature from serologic to DNA-based typing methods, "serologically equivalent" designations have been defined [81].

DNA-based typing methods vary according to the level of discrimination they provide in defining the nucleotide sequence of an HLA gene. When the DNA typing method allows the identification of a serologically defined HLA antigen-equivalent (e.g., HLA-A2),

Table 10.3 Models for natural killer immunoglobulin-like receptor (KIR) ligands in unrelated donor hematopoietic cell transplantation

Model	Mechanism	Ligand			Examples
		Recipient	Donor	Vector	
Mismatched ligand	Due to the donor–recipient HLA class I mismatch, the recipient's target cells lack the class I allotype present in the donor	C1, C1 and Bw4, Bw4	C1, C2 and Bw4, Bw6	No C2 in recipient; GVH	HLA-B15 versus B13 mismatched haploidentical donor and recipient: Donor B*27:05 (Bw4), C*01:01 (C1); B*15:01 (Bw6), C*04:01 (C2) Recipient B*27:05 (Bw4), C*01:01 (C1); B*13:01 (Bw4), C*03:02 (C1)
		C1, C2 and Bw4, Bw6	C1, C2 and Bw6, Bw6	No Bw4 in donor; HVG	HLA-B18 versus B52 mismatched haploidentical donor and recipient: Donor B*15:01 (Bw6), C*04:01 (C2); B*18:01 (Bw6), C*07:01 (C1) Recipient B*15:01 (Bw6), C*04:01 (C2); B*52:01 (Bw4), C*12:02 (C1)
Missing ligand	Despite HLA identity, host cells are missing the class I ligand to provide the inhibitory signal	C1, C1; Bw4, Bw4 or C1, C1, Bw4, Bw6	No C2 ligand for donor KIR2DL1No C2 ligand for donor KIR2DL1 and no Bw4 for 3DL1		Recipient B*13:01 (Bw4), C*03:02 (C1); B*27:05 (Bw4), C*01:01 (C1) or B*13:01 (Bw4), C*03:02 (C1); B*08:01 (Bw6), C*07:01 (C1)
		C1,C1; Bw6,Bw6			Recipient B*39:01 (Bw6), C*12:03 (C1); B*07:02 (Bw6), C*07:02 (C1)
		C2, C2; Bw4, Bw4 or C2, C2; Bw4, Bw6	No C1 for donor KIR2DL2		Recipient B*44:05 (Bw4), C*02:02 (C2); B*13:02 (Bw4), C*06:02 (C2) or B*44:05 (Bw4), C*02:02 (C2); B*15:01 (Bw6), C*04:01 (C2)
		C2,C2; Bw6, Bw6	No C1 for donor KIR2DL2 and no Bw4 for donor 3DL1		Recipient B*18:01 (Bw6), C*05:01 (C2); B*13:02 (Bw6), C*06:02 (C2)

C1, HLA-C group 1 allotypes: the KIR2DL2 and 2DL3 receptors recognize Ser77 and Asn80.
C2, HLA-C group 2 allotypes: the KIR2DL1 receptor recognizes HLA-C allotypes encoding Asn77 and Lys80.
Bw4: The inhibitory receptor KIR3DL1 recognizes the HLA-Bw4 epitope expressed on certain HLA-B and HLA-A molecules.
GVH, graft-versus-host; HVG, host-versus-graft.

the method is termed "low resolution." As described below, SSP methods and SSOP approaches that employ a restricted number of probes may provide only limited sequence information about a particular HLA gene, equivalent to that achievable by serology. HLA typing methods that provide information beyond the serologic level but short of the allele level are termed "intermediate resolution." For example, an SSP method that uses a comprehensive panel of PCR primers, or an SSOP method that employs a wider array of probes, might identify the presence of either HLA-A*02:01 *or* -*02:09 in an amplified DNA sample, but might be unable to discriminate one allele from the other. This intermediate-resolution result would be characterized as "HLA-A*02" or "HLA-A*02:01/09." Typing methods that generate nucleotide sequence information allowing the precise identification of an HLA allele (e.g., HLA-A*02:01) are termed "high resolution." High-resolution typing results may be achieved by direct automated sequencing of an HLA gene (*SBT*) or by the use of large panels of oligonucleotide probes that test all known regions of variability within a gene. In order to interpret HLA-typing results and select donors for transplantation, it is necessary to know whether the typing was carried out at low, intermediate or high resolution. A patient and donor who are "matched" for HLA-A and -B antigens by low-resolution typing methods may be mismatched for HLA-A and/or -B alleles (see Chapter 45). Histocompatibility guidelines for unrelated HCT have been revised to accommodate DNA-based typing methods [82].

SSP

SSP provides a simple and low-cost method for low-to-intermediate resolution of HLA alleles. The SSP methods employ a panel of PCR primers that can amplify specific HLA loci or alleles [54,83–86] (Figure 10.4) and KIR genes [87,88] (Figure 10.5). The SSP method is based on the design of PCR primers whose sequence is complementary to one or more nucleotide bases that distinguish HLA alleles, KIR alleles, or KIR genes. Depending on the need, panels of primers can be designed to distinguish the major serologically equivalent families at a given HLA locus; alternatively, primers can be designed to determine the specific allele among a family of alleles within a given serological family. For example, SSP typing methods can differentiate between HLA-A1, -A2, -A11, and so on. SSP primers can also identify the A*02:01 allele from the A*02:05 allele within the HLA-A*02 family. After PCR amplification with the primers, the products are electrophoresed on a gel. The presence of an amplified product is signaled by a dye and is evidence that the HLA allele is present. The HLA tissue type is determined by evaluating the patterns of positive and negative amplifications to the entire panel of primers (Figure 10.4.) When SSP primers are designed to specific polymorphisms that distinguish between KIR genes, then an amplified product is evidence that the KIR gene is present (Figure 10.5). SSP methods are highly cost-effective for ascertaining the presence of KIR genes and typing the serologically equivalent HLA alleles. SSP methods for comprehensive typing of HLA alleles are less cost-effective than probe- or sequencing-based methods, owing to the need for the large number of PCR reactions.

SSOP

SSOP methods provide high resolution of alleles and the capacity for increased throughput. SSOP methods for typing HLA alleles employ a solid-phase support to immobilize PCR-amplified products [55,56,89,90] (Figures 10.6 and 10.7). Similar SSOP-based methods have been developed to type KIR genes [91]. Oligonucelotide probes range between 15 and 30 nucleotide bases in length, and are complementary to known sequence polymorphisms of HLA alleles. The target DNA is PCR amplified, immobilized on a solid-phase support, and allowed to hybridize to the probes. When the probe has exact complementarity to the target DNA, the probe anneals to the target, and hybridization is detected by way of a marker that is attached to the probe. Alternatively, probes can be immobilized on a solid-phase support, with which the target DNA is allowed to hybridize. Whether the probe or the target is immobilized, either approach requires a comprehensive panel of probes that are descriptive for the family of HLA alleles being tested. Allele assignment is made by interpreting the reactivity of the target DNA to the entire panel of probes. SSOP methods provide information on positions known to be polymorphic; if a novel substitution is located in a region of an HLA sequence to which a probe is not designed, then that substitution escapes detection. A recent variation of probe-based typing technologies is the Luminex® system, which uses beads that are coated with oligonucleotides. After the target DNA is PCR-amplified, it is allowed to hybridize to the beads in a 96-well plate system. Hybridization of the target DNA with the beads is detected by way of fluorescent dyes. The use of plates that can handle up to 96 samples, robotics for sample handling, and automated data analysis permit efficient typing.

SBT

The only methods that permit comprehensive evaluation of an HLA or KIR sequence, nucleotide for nucleotide, are sequencing-based methods [57,58,92,93]. For HLA genes, SBT methods are highly accurate and powerful for uncovering novel variations. Among the most widely used SBT methods is automated fluorescent cycle sequencing. For HLA class I genes, exons 2, 3, or 4 can be separately PCR-amplified, or primers may be designed to amplify longer fragments containing both exons 2 and 3. For HLA class II genes, the polymorphic exon 2 is PCR-amplified. KIR genes contain 8–9 exons; PCR amplification may involve amplifying several overlapping groups of exons. Following PCR amplification, cycle sequencing is performed using fluorescently labeled primers or fluorescently labeled dideoxynucleotides. The sequenced templates are electrophoresed on a gel dedicated to an automated sequencer (Figure 10.8). Newer sequencing methods, known as "next-generation sequencing (NGS)" permit millions of single DNA molecules to be sequenced in parallel, and offer long clonal read lengths that enable the sequence of one exon to be linked to that of the neighboring exon, akin to phasing [94]. Allele assignments are made with the aid of software. A novel sequence-based approach for KIR genes used mass spectrometry to type 17 KIR genes and define novel alleles of KIR genes [95].

Donor selection

Donor selection begins with a full evaluation of available family members of the transplant recipient (Figure 10.2). A family study includes HLA typing of the father, mother, full siblings, and additional relatives, where indicated. The family study confirms the recipient's genotype and haplotypes, and provides information about the existence of genotypically matched siblings and/or haploidentical family members. When more than one equally suitable related donor is available, additional selection criteria including the number of HLA disparities on the mismatched maternal or paternal haplotype, and the presence or absence of disparity and of homozygosity for HLA KIR ligands, may be considered. When several equally matched unrelated donors are available, non-HLA factors, including donor age, parity, gender, and cytomegalovirus serostatus, may be considered in donor selection (Chapter 45).

For any donor who is HLA-mismatched to the patient, the vector of HLA incompatibility has biological meaning (Table 10.4). The concept of the vector or "direction" of HLA mismatching was shown by Anasetti and Hansen [96] in 1994 in risk of graft failure and acute GVHD in related haploidentical transplants. The vector of a mismatch can be defined for host-versus-graft (HVG) and GVH alloreactivity. The presence of donor antigens or alleles not shared by the recipient determines HVG allorecognition. The presence of recipient antigen or alleles not shared by the donor provides the immunologic basis for GVH allorecognition. Mismatching between a donor and recipient can be described as "bidirectional" if both HVG and GVH vectors are present at a given HLA locus. Mismatching is called "unidirectional" if one but not the other vector is present. Unidirectional mismatching in the GVH vector occurs when the donor is homozygous and the recipient is heterozygous and shares one allele or antigen with the donor (e.g., patient A*02:01, *02:05 versus donor A*02:01, *02:01). Unidirectional mismatching in the HVG vector occurs when the patient is homozygous and the donor is heterozygous and shares one allele with the patient (e.g., patient A*02:01, *02:01 versus donor A*02:01, *02:05).

Table 10.4 Vector of HLA mismatch

Vector	Definition	Examples	
		Donor	Recipient
HVG	Presence of donor alleles or antigens not present in the recipient	B*08:01,44:02[a]	B*08:01,44:05
		B*08:01,44:02[b]	B*08:01,08:01
GVH	Presence of recipient alleles or antigens not present in the donor	B*08:01,44:02[a]	B*08:01,44:05
		B*08:01,08:01[b]	B*08:01,44:05

GVH, graft-versus-host; HVG, host-versus-graft.

[a] These combinations contain bidirectional (both HVG and GVH disease) mismatch vectors.

[b] Unidirectional mismatches.

Haploidentical siblings may be variably mismatched for the non-shared haplotype depending on whether the maternal and paternal HLA haplotypes fortuitously encode the same HLA antigen(s) or allele(s). The haplotypes of a child may be described in relation to the mother ("inherited maternal HLA antigens") or father ("inherited paternal HLA antigens"). Non-inherited maternal antigens (NIMAs) or non-inherited paternal antigens (NIPAs) refer to the HLA antigens expressed on the non-shared haplotypes. NIMA and NIPA have clinical significance. Exposure to NIMA in utero is tolerizing, whereas that to NIPA is immunizing. Donor-specific suppression of T-cell responses against NIMA is associated with lower risks of acute and chronic GVHD and transplant-related mortality after transplantation from mother to child compared with father to child [97]. In addition to maternal and paternal sharing of HLA antigens, selection of haploidentical family members can also include consideration for mismatched or missing HLA KIR ligands encoded by HLA-B, -C and certain -A alleles. For these purposes, the availability of high-resolution typing of HLA class I alleles of the recipient provides the necessary information to determine whether a patient is Bw4 positive or negative, and whether the recipient is C1/C2 heterozygous, C1/C1 homozygous, or C2/C2 homozygous.

Histocompatibility testing for unrelated donors includes five loci: *HLA-A*, *-B*, *-C*, *-DRB1*, and *-DQB1*. Donor typing and matching for the two determinants at each locus give rise to the 10 possible alleles considered relevant in HCT. Donors and recipients who have the same 10 alleles at the five loci are commonly described as "10/10 allele-matched." The term "8/8" refers to high-resolution matching at the four loci *HLA-A*, *-B*, *-C*, and *-DRB1*. The term "6/6" refers to three typed loci *HLA-A*, *-B*, and *-DRB1:* however, the resolution may not necessarily be high at all three genes as in the case of cord blood transplantation, where HLA-A and -B typing is usually performed at low resolution and -DRB1 at high resolution. In addition to HLA matching of unrelated donors, pretransplant assessment of the presence of anti-HLA antibodies in recipient serum is vital, as a positive cross-match places the patient at high risk for non-engraftment [46,47].

Conclusions

Genes of the HLA system encode a complex array of histocompatibility molecules that play a central role in immune responsiveness and in determining the outcome of tissue transplantation. The primary goal of histocompatibility testing for patients undergoing HCT is the identification of a suitable HLA-matched donor to reduce the risk of post-transplant complications resulting from HLA incompatibility. The recent advent of DNA-based methods that allow discrimination of HLA genes at the allele level has enhanced our ability to perform typing and matching with speed and precision. The future of histocompatibility testing in support of allogeneic transplantation will incorporate consideration not only of the classical HLA genes, but also of functional variation that is linked to HLA loci on haplotypes, and KIR genes. Ultimately, the key to understanding the histocompatibility barrier in transplantation will require information on the content of the MHC region and the organization of that genetic variation on haplotypes.

CHAPTER 11

Natural Killer Cells and Allogeneic Hematopoietic Cell Transplantation

Michael R. Verneris and Jeffrey S. Miller
University of Minnesota, Minneapolis, MN, USA

Introduction

Natural killer (NK) cells are large, granular lymphocytes that express CD56 (neural adhesion protein, NCAM) and lack the CD3 receptor (i.e., $CD56^+CD3^-$). NK cells make up ~10–15% of the peripheral blood (PB) lymphocytes and are a critical component of the immune system. NK absence or dysfunction results in recurring, life-threatening viral infections [1]. NK cells have also been implicated in tumor surveillance since they preferentially kill malignant cells while sparing normal, non-transformed cells. This is accomplished by displaying numerous non-rearranged, germline surface receptors with unique specificity. These receptors detect the presence or absence of MHC class I and also "stress" receptors, both of which are perturbed during malignant transformation and/or viral infection. In addition to cytotoxic responses, NK cells are an important source of cytokines, which feed back to the adaptive immune system including T cells, B cells, and dendritic cells (DCs). NK cells directly interact with these cells and thereby shape adaptive immune responses. As one of the earliest lymphocyte populations to recover after allogeneic hematopoietic cell transplantation (HCT), NK cells may be important in the early immune events that occur after HCT. The purpose of this chapter is to provide up-to-date information on NK-cell biology as it relates to allogeneic HCT. Since there are both similarities and differences between murine and human NK cells, we will focus mainly on human studies but, where necessary, relevant murine information will be included.

NK-cell subpopulations: $CD56^{bright}$ and $CD56^{dim}$ NK cells

NK cells have been subdivided into two major subsets on the basis of CD56 staining intensity and the expression of the low-affinity immunoglobulin (Ig) receptor CD16 ($F_c\gamma RIII$). Approximately 85–90% of all NK cells express CD16 and the majority of these cells also show dim CD56 expression. Consequently, the $CD56^{dim}CD16^+$ fraction of NK cells accounts for the bulk of the circulating NK cells. A smaller fraction (~10–15%) of NK cells shows high CD56 expression. $CD56^{bright}$ cells have low to absent CD16 expression (i.e., $CD56^{bright}CD16^{-/+}$). These two NK-cell subsets differ in their responses to exogenous cytokine stimulation, cytotoxicity, and cytokine production, suggesting that they may have distinct roles in immune responses (reviewed in [2]).

Cytokines, such as IL-2 and IL-15, are essential for the growth, development, and activation of NK cells. For these cytokines to transmit intracellular signals, the expression of a trimeric protein complex is required. This complex is made up of the common γ chain (CD132) and the β chain (CD122) in addition to a "private" chain [IL-2α (CD25) or IL-15α]. Whereas $CD56^{bright}$ and $CD56^{dim}$ NK cells do not differ in the expression of the common γ chain (CD132), there are differences in the expression of the other two chains (α and β) of the IL-2 receptor. Only $CD56^{bright}$ NK cells display all three chains of the high-affinity IL-2 receptor (αβγ) and proliferate in response to picogram quantities of IL-2 [3–5]. In contrast, $CD56^{dim}$ NK cells express only the β and γ chains of the IL-2 receptor and show poor proliferation under these same conditions [3–5]. About half of the $CD56^{bright}$ NK cells express the stem-cell factor receptor (CD117, c-KIT) and the IL-7 receptor (CD127) and respond to these cytokines, whereas $CD56^{dim}$ lack these receptors and are therefore insensitive to these early-acting cytokines.

$CD56^{bright}$ and $CD56^{dim}$ NK cells also differ functionally. Compared with $CD56^{dim}$ NK cells, $CD56^{bright}$ cells produce significantly more INF-γ, TNF-α, TNF-β, GM-CSF, IL-10, and IL-13, following activation with monocyte derived cytokines, such as IL-12, -15 and -18 [2,6,7], yet $CD56^{dim}$ NK cells produce cytokines in response to target-cell engagement. In contrast, $CD56^{dim}CD16^+$ NK cells have ~10-fold more perforin and granzyme B than $CD56^{bright}$ cells [7]. Accordingly, freshly isolated $CD56^{dim}$ NK cells have higher cytotoxicity than the $CD56^{bright}CD16^-$ cells [4]. However, after short-term culture in cytokines, both NK-cell subpopulations show similar killing ability [4]. As mentioned above, $CD56^{bright}$ and $CD56^{dim}$ NK cells differ in the expression of the low-affinity Ig receptor CD16. Therefore, $CD56^{dim}CD16^+$ NK cells have the ability to recognize and kill antibody-coated targets through antibody-dependent cellular cytotoxicity (ADCC). Antibody-coated B cells (anti-CD20; rituximab), breast cancer cells (anti-Her2neu; trastuzumab) and osteosarcoma cells (anti-EGFR; cetuximab) are more effectively killed by NK cells [8–10]. Collectively, the above studies suggest that these two NK-cell subpopulations have distinct immune functions, with $CD56^{bright}$ NK cells producing cytokines and the $CD56^{dim}$ NK cells having more of the cytotoxic/effector role. In addition, CD16 delivers a potent activating signal on $CD56^{dim}$ NK cells; therefore, novel strategies to impart specificity to NK cells are being contemplated through the use of CD16 antigen bispecific immune engagers.

NK cell Cytotoxicity

A hallmark feature that distinguishes NK cells from most other cell types is the ability to kill malignant cell lines (K562) directly without prior antigen priming or cytokine stimulation. One of the first steps in NK-cell cytotoxicity is the establishment of a stable conjugate between the NK cell and the target cell, known as an “immune synapse” (IS). Studies have demonstrated that the early events in the creation of the IS involve the binding of CD2 and β_2-integrins (CD11a and CD11b) on the surface of NK cells with their ligands on target cells. These proteins organize into a ring-like structure at the point of contact between the NK cell and the target cell, forming the periphery of the IS [11]. Following this numerous NK-cell surface receptors are recruited to the center of the IS. Assuming that the balance of activating signals is greater than inhibitory receptor signals, actin polymerization facilitates the redistribution of cytotoxic granules to the center of the IS [11], for eventual release.

Target killing by NK cells occurs through two separate mechanisms: (1) the granule release pathway and (2) the membrane expression of TNF superfamily death receptors. NK cells contain lysosomal granules that store a number of cytotoxic proteins, including serine proteases (granzymes A, B, H, K, and M), perforin, and granulysin. Following activation, these granules are redistributed within the NK cell and released into the IS. Once released, these serine proteases enter the target cell and induce apoptosis. The two best characterized membrane receptors involved in the second method of killing are FasL and TNF-related apoptosis-inducing ligand (TRAIL) [12]. FasL binds to the Fas receptor (CD95), which is broadly expressed, including on human hepatocytes. In the case of TRAIL, two receptors (DR4 and DR5) are selectively expressed by malignant cells [13]. Binding of either FasL or TRAIL to the surface of malignant target cells results in activation of caspase-dependent death pathways, culminating in target cell apoptosis. Numerous malignant target cell lines and clinical acute leukemia and myelodysplastic syndrome (MDS) samples express the Fas or TRAIL receptors [14–16].

MHC-specific NK-cell receptors: KIR and CD94/NKG2A

The “missing self” hypothesis

There has been significant progress in the understanding of the receptors that control NK-cell triggering. Through the pioneering work of Karre and Ljunggren, it was noted that a subclone of a malignant cell line was more sensitive to NK killing than the parental line. Further experiments showed that the more sensitive subclone had lost MHC class I expression. This observation lead to “the missing self” hypothesis, which predicted that NK cells are inhibited by self-MHC [17]. Such a hypothesis reasonably explained how NK cells might be tolerant of normal tissues, but could also kill malignant or virally infected targets with downregulated or lost MHC class I. Since this original observation, MHC class I-specific receptors have been identified on NK cells from a number of species (reviewed in [18,19]). Interestingly, some of these receptors are unique between mouse and humans, suggesting their recent (and parallel) evolution, perhaps in response to infectious challenges [20]. In humans, two groups of MHC-specific receptor systems have been identified and characterized: (1) the killer Ig receptor (KIR) family and (2) a c-lectin receptor made up of a heterodimeric complex between NKG2A, -C, and -E molecules and CD94 (Figure 11.1).

KIR receptors

The KIR gene locus is present on human chromosome 19q13.4 and comprises a multigene family of up to 15 individual cell surface receptors (reviewed in [19–21]). KIR genes are further subdivided based on the structure of both the extracellular and intracellular

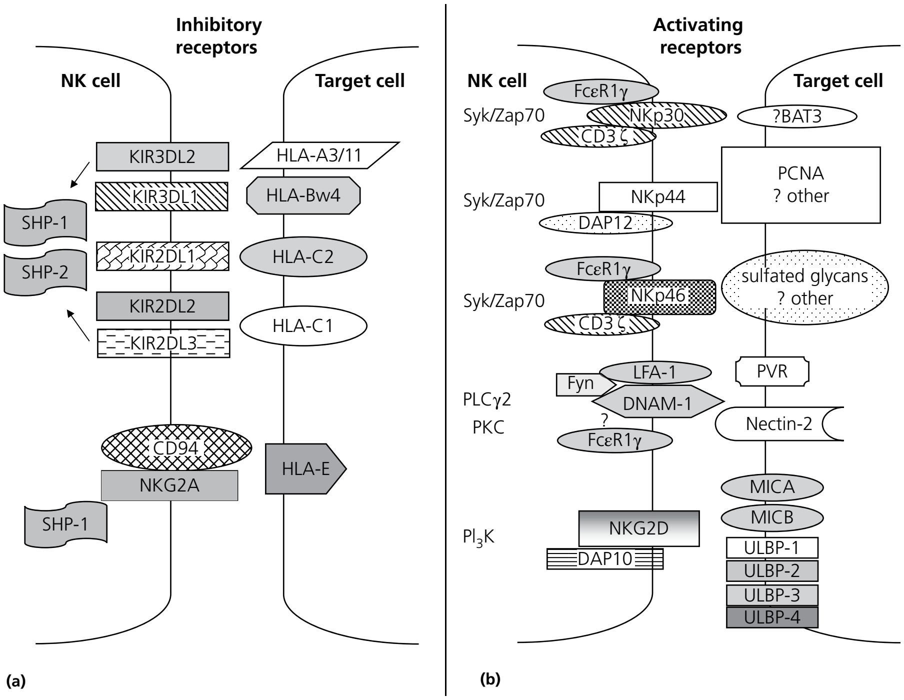

Figure 11.1 NK cell receptors and their ligands. Shown are the various inhibitory receptors (a) and the activating receptors (b) and their ligands. Also shown are the associated adapter proteins and the intracellular signaling pathways that are activated.

	Gene frequency
KIR2DL1	97.8
KIR2DL2	51.2
KIR2DL3	91.9
KIR2DL4	100
KIR3DL5	51.3

KIR2DS4	96.1
KIR2DS5	32.9
KIR3DL1	96.0
KIR3DL2	100
KIR3DL3	100
KIR3DS1	38.4

Figure 11.2 The complexity of KIR. Individuals vary in the number and type of genes that they express and data are shown for >450 patients types (unpublished observations) (left). In addition, there is considerable diversity within an individual KIR gene at the nucleotide level (i.e., polymorphisms) (middle) and at the cellular level (right).

domains. These domains regulate ligand binding and signaling, respectively. In general, KIR genes are referred to as either KIR2D or KIR3D, depending on the number of Ig domains in the extracellular portion. KIR receptors also vary with respect to the length of their intracellular signaling domains and are classified as either "long" or "short." KIR with long intracellular signaling domains contain ITIM (immunoreceptor tyrosine-binding inhibition motif) regions that recruit inhibitory signaling proteins, such as SHP-1 and SHP-2 [22,23], resulting in an significant attenuation of NK cell activation (reviewed in [21]). In contrast, KIR with short tails lack ITIMs and instead associate with adapter proteins, such as DAP12, to mediate signals that activate NK cells [24]. Thus, KIR with *short* intracellular tails are activating whereas those with *long*, ITIM-containing regions are inhibitory. A nomenclature committee has assigned a cluster of designation (CD) number of CD158 for the KIR genes with individual loci designated by a small letter ± a number (e.g. KIR3DL1 = CD158e1] [25].

Given the vast polymorphism of human MHC, it was difficult to conceive how a single KIR could recognize multiple MHC alleles from different individuals. X-ray crystallography shows that like the T-cell receptor (TCR), KIR interacts with the face of the MHC molecule, but more to the right-hand side and outside the peptide-binding groove [26]. This corresponds to a motif conferred by a conserved stretch of amino acids at positions 77–83 of HLA-B and at position 80 of HLA-C [19]. Thus, despite the vast polymorphism of MHC class I alleles, alignment of this amino acid stretch falls into two different groupings, known as Bw4 and Bw6 for HLA-B. Likewise, depending upon whether there is an asparagine (Asn) or a lysine (Lys) at position 80, HLA-C can be divided into C1 and C2 groups, respectively. These dimorphisms in HLA-B and -C convert the recognition of a highly diverse, multi-allelic MHC class I molecules into a biallelic system. However, further complexity is present since polymorphism of KIR genes and HLA determines the strength of inhibitory signaling. To date, HLA-Bw6 alleles do not appear to be recognized by KIR. In contrast, both HLA-C1 and -C2 are ligands for different KIR receptors (KIR2DL2/KIR2DL3 and KIR2DL1, respectively). While the specificity of many of the inhibitory KIR receptors is known to be MHC class I, the KIR family also contains receptors for which the specificity is not known, including most of the activating (or short) KIR, except for KIR2DS2 that binds HLA-C2 at low affinity.

The KIR gene locus is a multigene family; however, individuals vary with respect to the number of KIR genes that they possess (see Figure 11.2). By sequencing the KIR region of 68 individuals, Uhrberg et al. found that all individuals contain a set of framework genes including KIR3DL3, KIR2DL4, and KIR3DL2. They could also discern common haplotypes with varying gene content, called haplotype A and B [27]. Although both haplotypes contained inhibitory and activating KIR genes, the A haplotype showed fewer genes, typically only one activating receptor (KIR2DS4). In contrast, the B haplotype contained the full complement of inhibitory genes, but also expressed multiple activating KIR genes [27]. These haplotypes are present in relatively equal frequencies in Caucasians [28]. A study by Cooley et al. showed that donors expressing KIR B genes and, in particular, the centromeric portion of the KIR B haplotype ("cen B/B" homozygotes) had a dramatically lower rate of myeloid leukemia relapse and improved survival in multivariate analysis [29]. Similarly to a number of other studies, these findings were found only in myeloid leukemia and not in patients with lymphoid leukemia. Thus, NK-cell-mediated graft-versus-leukemia effect (GVL) appears to be mainly myeloid leukemia specific and not all donors are equivalent with respect to GVL. It may be possible to select NK "super donors" for myeloid leukemia transplantation.

To add further complexity to the KIR system, each gene shows considerable polymorphism [27] and some are functionally important. For example, KIR3DL1*004 is not expressed on the cell surface, so it cannot recognize its respective Bw4 ligand [30]. Still further complexity is appreciated since KIR and MHC exist on separate chromosomes and do not co-segregate during meioses. This leads to a situation where some individuals express receptors for ligands they do not have [27]. Thus, KIR is clonally distributed on individual NK cells, resulting in a complex system of individual NK cells, each expressing a different combination of KIR receptors (Figure 11.2). This creates a network of NK cells capable of recognizing subtle changes in a single MHC gene on target cells. Although beyond the scope of this chapter, KIR are not restricted to NK cells and have also been observed on mainly CD8$^+$ T cells of memory phenotype and may play a role in such responses.

NKG2A

NKG2A is the other MHC-specific inhibitory receptor expressed by the majority of NK cells. For NKG2A to be presented on the cell surface, it must associate with the CD94, creating the heterodimeric protein complex CD94/NKG2A [31]. Like inhibitory KIR, NKG2A contains two ITIM regions in the cytoplasmic tail segments [31] and ligation of this complex results in strong inhibition of cytotoxicity [32]. In contrast to KIR, which recognizes the classical MHC class I proteins (HLA-A, -B, and -C), CD94/NKG2A recognizes HLA-E [33,34]. Remarkably, a small segment of the leader peptide of classical MHC class I (amino acids 3–11) is complexed within HLA-E and stabilizes HLA-E surface expression, which can bind to CD94/NKG2A [32,33]. Thus, whereas KIR *directly* assesses the MHC class I expression of the surface of target cells, CD94/NKG2A both directly assesses the HLA E expression, and also *indirectly* determines MHC class I expression since, if HLA-A, -B, and -C are not expressed, then the leader sequence is not presented in the groove of HLA-E and the expression of HLA-E is reduced.

NKG2A is one member of the NKG2 gene family found within the NK cell gene cluster [35]. Other members of this gene family have also been investigated, including NKG2C, NKG2E, and NKG2D (see below). Analogous to "long' and "short" KIR, which have similar extracellular domains but differ in the intracellular signaling domains, NKG2C shares considerable homology with the extracellular portion of NKG2A and also recognizes HLA-E. In contrast to NKG2A, both NKG2C and NKG2E lack ITIMs and mediate NK-cell activation through association with DAP12 [36]. NKG2C is of increased interest as expression increases after exposure to viruses such as hantavirus or cytomegalovirus (CMV).

NK-cell-activating receptors: NKG2D, natural cytotoxicity receptors, and DNAM-1

NKG2D

Unlike other NKG2 members (NKG2A, -C, -E, etc.) that form a heterocomplex with CD94, NKG2D exists as a homodimer [37,38]. Interaction of NKG2D with its ligands (see below) delivers signals that can override inhibitory KIR. NKG2D is not able to signal directly and uses the adaptor protein DAP10 to transmit intracellular signals (Figure 11.1] [37]. DAP10 in turn recruits the p85 subunit of the PI3 kinase protein [37]. Additionally, NKG2D triggering leads to cytokine production (TNF-α, GM-CSF, IFN-γ) [39].

NKG2D binds to two groups of self-proteins which appear to be preferentially expressed on distressed cells, such as malignant cells. The first group of NKG2D ligands are MHC class I polypeptide-related sequence A and B (MICA and MICB). These two closely related MHC-like proteins are within the MHC gene complex, approximately 46 kb centromeric to HLA-B. The promoter region of MICA contains a heat shock protein-like element, similar to HSP70, and accordingly, MICA and MICB are expressed during cell division, radiation-induced genotoxic stress, malignant transformation, and following infections (viral and bacterial) [40–43]. MICA also shows limited expression on normal cells with the highest level of expression in the gastrointestinal tract, a target tissue for graft-versus-host disease (GVHD) [40]. Like MHC class I, MICA and MICB are polymorphic with approximately 58 and 18 individual alleles, respectively. Some of these alleles show differing binding affinities for NKG2D [44], again reflecting the complexity of NK receptor–ligand interactions. The other group of ligands recognized by NKG2D is the UL16-binding proteins, ULBP1–6, which have minimal homology to the MICA/B proteins. Like MICA and MICB, ULPB1–6 are also expressed on malignant tissues and freshly isolated malignant cells [45,46].

Natural cytotoxicity receptors (NCRs)

The natural cytotoxicity receptors (NCRs) were identified by Moretta's group after raising monoclonal antibodies (mAbs) against NK clones and then screening these antibodies for the ability to trigger NK cytotoxicity. Using this approach, these investigators identified three functionally similar, but structurally separate, NK-activating receptors. Collectively, these receptors have been referred to as NCRs since they play a major role in NK-cell recognition of malignant targets. The first of these receptors, NKp46, is identified as a type I transmembrane receptor of the Ig superfamily located within the leukocyte receptor complex on chromosome 19 (19q13.4) [47]. The second receptor, NKp30, is a V-type receptor found in the TNF cluster of the MHC gene complex on chromosome 6 [48]. Both NKp30 and NKp46 are expressed on nearly all resting and activated human NK cells. The third NCR, NKp44, is found only on IL-2-activated NK cells. Similarly to NKp30, the NKp44 gene is also present within the TNF cluster of the MHC gene complex on human chromosome 6.

Like other NK cell receptors, NKp30, -44, and -46 are not able to signal directly and rely upon adaptor proteins to transmit activation signals. NKp30 and NKp46 use CD3ζ and FcεR1γ, whereas NKp44 associates DAP12. Ligation of these receptors induces Ca^{2+} flux, cytotoxicity, and cytokine release. NCRs are critically important in recognition and killing of numerous malignant targets (reviewed in [49]). Antibody blockade of a single receptor shows some attenuation in cytotoxicity; however, blockade of two or more of the NCR receptors results in a significant reduction in cytotoxicity, suggesting that these receptors cooperate with one another. Although most individuals have NK cells with strong NKp30 and NKp46 expression, some show an NCR^{dim} phenotype and this correlates with a reduction in NK cell cytotoxicity [48,50].

NKp44 and NKp46 recognize viral products, such as hemagglutinin [51]. Likewise, Chisholm and Reyburn showed that vaccinia virus-infected cells become susceptible to NK cytolysis. Using solublized receptors, they further demonstrated increased expression of NKp30, NKp44, and NKp46 ligands [52]. Whether these ligands are self-proteins induced by viral infection or viral proteins themselves remains to be determined. Such ligands may be increased on cells that have undergone malignant transformation, perhaps like the NKG2D ligands MICA and MICB. Further support for NCR recognition of self-proteins is that NKp30 interacts with immature DCs through NKp30 [53], implying that DCs express a ligand for NKp30. The HLA-B-associated transcript 3 (BAT3) is expressed on DCs and appears to be a ligand for NKp30 [54]. Additional studies suggest that MHC-related receptor B7H6 is also a ligand for NKp30.

DNAM-1

DNAX accessory molecule-1 (DNAM-1, CD226) is a receptor expressed by both NK cells and T cells and is also involved in cytotoxic triggering [55]. The ligands recognized by DNAM-1 include the polio virus receptor (PVR, CD155) and nectin-2 (CD112) and NK cell cytotoxicity of neuroblastoma and leukemia cells correlate with PVR and/or nectin-2 expression [42,56,57]. For resting NK cells to become activated, DNAM-1 cooperates with other NK-cell receptors, such as NKp46 and -2B4, to induce Ca^{2+} flux, cytokine secretion (IFN-γ and TNF-α), and cytotoxicity [58].

NK killing of leukemia

NK-cell recognition of leukemia and MDS is of particular importance to the field of allo-HCT, since understanding such processes may allow for augmentation of GVL. Most in vitro studies show that acute myeloid leukemia (AML) patient samples are more sensitive than acute lymphoblastic leukemia (ALL) blasts. Considering that NK-cell cytotoxicity is a balance between the inhibitory and activating NK-cell receptor signaling, the relatively lower cytotoxicity of ALL lines could be accounted for by either high expression of inhibitory receptor ligands (i.e., HLA class I) or low expression of activating receptor ligands, or a combination of both. In fact, compared with AML blasts, ALL patient samples express higher amounts of MHC class I (i.e., KIR-L), which negatively modulate NK killing [42]. There is a significant correlation between the NK killing of ALL and the density of HLA class I (the higher the HLA expression, the less is the killing) [59]. Moreover, when high amounts of HLA class I were present on ALL blasts and KIR-L mismatched donor NK cells were used (see below), killing increased [59].

Despite a higher amount of HLA class I on ALL blasts relative to AML blasts, most malignant cells show a *reduction* in HLA relative to normal cells, perhaps as a consequence of T-cell selective pressure. Using a large panel of HLA-A and -B allele-specific mAbs and a panel of 32 patient samples [chronic myelogenous leukemia (CML), ALL, and AML), Demanet et al. showed that 65% of samples had a reduction in one or more HLA class I relative to normal lymphocytes. Interestingly, however, when they grouped the downregulated HLA-B alleles into the Bw4 and Bw6 allospecificities, they observed downregulation of significantly more Bw6 than Bw4 alleles [60]. Considering that the inhibitory KIR receptor KIR3DL1 recognizes Bw4 but not Bw6 alleles, this might suggest that such leukemia cells were selected for escaping *both* NK-cell and T-cell surveillance. On a related note, Verheyden et al. tested whether patient KIR genes might be associated with leukemia risk. In their study of 96 patients with acute and chronic leukemia and 148 controls, they found that leukemia patients were more likely to express KIR2DL2 and be heterozygous for the HLA-C-specific KIR haplotype. Such patients would express most, if not all, inhibitory KIR (and their ligands), creating a situation of excessive NK cell restraint that might favor subsequent escape of leukemia from immune surveillance [61]. In another patient cohort, the same group found that chronic lymphoid leukemia (CLL) and AML patients were more likely to express a particular KIR and its corresponding ligand (MHC class I) compared with controls, suggesting that NK cells are involved in the surveillance of malignancy and the interaction between KIR and its corresponding MHC can inhibit responses [62]. Similar observations have been made in the progression to HIV [63].

NK cells also require signals from the activating receptors to lyse targets and their expression on malignant cells may predict sensitivity to NK killing. For example, Pende and co-workers found that the NKG2D ligands ULBP1–3 were present on T-cell ALL lines and patient samples, but were essentially absent on pre-B ALL patient samples [41,42]. Likewise, only a minority of AML samples (7/25) expressed NKG2D ligands [42]. In contrast, Salih et al. found that >50% of AML, ALL, and CML patient samples expressed NKG2D ligands, perhaps reflecting different reagents used in these assays [46]. Importantly, MICA can be shed from the cell surface and can be found in patient sera [46,64]. Soluble MICA can act as a decoy by binding to NKG2D and inhibiting receptor function and leukemia recognition. Accordingly, surface expression of NKG2D is lower in newly diagnosed AML patients [65]. The DNAM-1 ligands (PVR and nectin-2) were present on most AML patient samples and to a lesser extent on ALL samples. Using individual patient samples, the involvement of DNAM-1 in NK-cell cytotoxicity of these targets was confirmed [42].

Most individuals express significant amounts of NCRs on their NK cells, constituting an NCR^{bright} phenotype. However, a minority (~10–15%) of normal donors show low NCR expression with an NCR^{dim} phenotype [66]. This NCR^{dim} phenotype is associated with reduced in vitro natural cytotoxicity. At the time of diagnosis, >60% of individuals with AML showed an NCR^{dim} phenotype [67]. As these patients were treated and entered hematological remission, most reacquired an NCR^{bright} phenotype, suggesting that leukemia results in receptor downmodulation, perhaps owing to the release of soluble NCR ligands or the elaboration of cytokines that downmodulate NCR expression (i.e., TGF-β or IL-10). However, other investigators have observed that NKp46 was not different from controls at the time of diagnosis [65].

Methods to overcome the resistance of leukemia to NK-cell cytotoxicity have also been explored. For instance, poor baseline NK-cell killing of autologous ALL blasts could be enhanced following cytokine stimulation (IL-2, -12 and -15) and culture in the presence of lymphoblast cell lines (LCLs) that activate NK cells [68]. To redirect NK cells to ALL, Imai et al. transduced NK cells with a chimeric antigen receptor (CAR) made of the external portion of a CD19 mAb and the internal signaling domains of CD3ζ and 4-1BBL. NK cells expressing this CAR showed marked proliferation, activation, and killing of NK-resistant ALL cell lines and patient samples [69]. This approach is limited by the need to introduce the CAR into NK cells, which are inherently resistant to retroviral transduction. To overcome this, Gleason et al. used single-chain variable fragments (scFvs) which recognize CD16 and CD19 (or CD22] to redirect NK cells to B-cell malignancies [70]. These CD16 × CD19 reagents potently enhance NK-cell cytotoxicity through direct activation of CD16 (resulting in granule release and cytokine production) and perhaps by bringing NK cells in close contact with malignant B cells by simulating an IS. Other approaches that have been tested to enhance NK killing of malignant cells include the use of chemotherapy to make blasts better targets. For example, treatment of AML blasts with a cocktail of differentiation agents (5-aza-2-deoxycytidine, trichostatin, vitamin D_3, bryostatin-1, and all-*trans*-retinoic acid) led to an induction of the NKG2D ligand ULPB1, which, in turn, enhanced NK-cell killing of AML targets [71]. Similarly, the histone deacetylase inhibitor trichostatin A increased NKG2D ligands (MICA and -B) on leukemic blasts and enhanced NK-cell killing [72]. In addition, IFN-γ led to a marginal increase in NCR ligands in AML patient samples and increased cytotoxicity [45].

NK-cell development from hematopoietic progenitor cells

Like other hematopoietic cells, human NK cells are derived from CD34$^+$ progenitor cells. Cytokines such as IL-2, -3, -7, and -15, stem cell factor, and FLT-3L facilitate the in vitro differentiation of such progenitor cells along the NK-cell lineage [73]. Of these cytokines, only IL-15 is required for NK-cell development, since IL-15$^{-/-}$ mice are devoid of NK cells [74]. In contrast, mice engineered to overexpress IL-15 (IL-15 transgenic mice) develop uncontrolled lymphoproliferation in both the CD8 T cell and NK compartments [75]. Thus, although IL-15 does not act solely on NK cells, it plays a central role in NK-cell homeostasis. In addition, NK-cell development is critically dependent upon stromal cells. Uncommitted, CD34$^+$CD38$^-$ cells cultured in the presence of cytokines show marginal NK-cell differentiation; however, both NK-cell maturation and expansion are significantly improved if the same progenitor cells are cultured in the presence of fetal liver stromal cell lines (and cytokines) [76]. Such augmentation of NK-cell development occurs in a contact-dependent manner [76]; however, the receptor–ligand pairs involved in this process remain to be identified. Thus, both the local environment and cytokine milieu influence NK-cell development.

A recurring paradigm in hematopoietic cell development is the progressive acquisition and loss of surface receptors during development, which can be used to functionally characterize distinct developmental stages of differentiation (see Figure 11.3]. Such a schema for human NK-cell development has been proposed (reviewed in [77]). The earliest antigens expressed on CD34$^+$ progenitors that mark enhanced potential to develop into NK cells include CD7, CD10, CD45RA, CD122, and integrin β_7 [77]. Such progenitors, referred to as Stage I or pro-NK cells, show increased capacity to differentiate into NK cells under the influence of the above-mentioned cytokines, with less of a need for stromal support, suggesting that cells that bear these receptors are committed to the NK-cell lineage. Following this, NK cell progenitors transit through a pre-NK (Stage 2) and immature NK cell (Stage 3) steps, characterized by the loss of surface proteins expressed on immature progenitors (CD34 and CD38) and acquisition of cytokine receptors (IL-3R and IL-7R) and adhesion molecules (LFA-1). Finally, differentiating NK progenitors acquire additional activating receptors (NKp30, -44, and -46, and NKG2D) in addition to the inhibitory receptor CD94/NKG2A in the CD56^{bright} stage (Stage IV) of NK-cell development and eventually KIR is expressed by CD56^{dim} NK cells (Stage V). Although a similar set of differentiation steps have been identified in the murine bone marrow, the location of NK-cell differentiation in humans appears to occur in secondary lymphoid tissue such as lymph nodes and tonsils [78,79].

Innate lymphoid cells (ILCs)

Recently, it has been proposed to reclassify NK cells as part of a larger group of cells that have now been referred to as innate lymphoid cells (ILC) [82]. Although NK cells are the best described ILC cells (ILC1), other cell types within this family have also been characterized, including type 2 ILCs (ILC2, natural helper cells or nuocytes [80]) and ILCs that express the retinoic acid receptor-related orphan receptor-γt (RORγt) transcription factor (RORγt$^+$ ILCs) [81,82]. Similarly to T-cell populations, ILC cells have been defined by transcription factor expression, which dictates function. For instance, ILC1 express T-bet and produce IFN-γ and TNF-α following IL-12 and IL-18 stimulation. ILC2 cells express the transcription factor ROR-α and secrete Th2-associated cytokines (IL-5 and IL-13) following extracellular parasite infection [80,83]. As the name implies, RORγt$^+$ ILCs express the RORγt transcription factor and produce IL-22 (ILC22) and/or IL-17 in response to IL-1β and IL-23, released during bacterial infections and/or gastrointestinal tract injury [84,85]. These latter cells exist within the Stage III NK progenitor fraction (Figure 11.3) and whether these cells are a unique and stable cell lineage or they give rise to conventional NK cells is debated. Of interest to the blood and marrow transplant community, RORγt$^+$ ILC3 cells mediate lymphoid tissue development during fetal life and its regeneration in adult life [81,86]. At present, the kinetics of recovery of these cells after allo-HCT are unknown. Given their properties, adoptive transfer of RORγt$^+$ ILC cells has the potential to accelerate post-transplant immune responses against infectious challenges and malignant disease.

Figure 11.3 Stages of NK-cell and innate lymphoid cell development. As NK cells develop from progenitor cells they lose and acquire surface receptors. Shown are some of the hallmark receptors and functional properties of developing NK cells. Not shown is the ontonogy of the CD94$^-$NKG2A$^+$ NK cells [89,143]. How these cells fit into the current "linear" schema of NK-cell development is unknown. Also shown is a concept that ILC cells share some phenotypic features with conventional NK cells and may give rise to conventional NK cells (denoted by the arrow with the question mark). Source: adapted from Freud and Caligiuri 2006 [77].

Development of NK-cell self-tolerance

The mechanism by which NK cells acquire self-tolerance has been referred to as "NK-cell education." Several models have been proposed that integrate inhibitory receptor signaling with the acquisition of effector functions. "Licensing" describes a terminal differentiation step by which NK cells only acquire mature function when they receive an appropriate signal via an inhibitory receptor ligating with self-MHC [87,88] Thus, human NK cells lacking inhibitory receptors are hyporesponsive [89]. In support of this, in vitro differentiation models show that NK cells acquire functionality (killing and cytokine production) only after the acquisition of CD94/NKG2A [90]. Thus, NK self-tolerance may be the result of a coordinated genetic developmental sequence during which mature NK function is synchronized with the acquisition of adequate expression of self-inhibitory molecules. However, murine HCT experiments show that transfer of mature NK cells into strains with differing MHC class I molecules rapidly results in either the activation or inhibition of cytotoxicity [91,92]. These studies have important implications for human HCT studies and suggest that licensing is not the only developmental process and that the function of mature NK cells can change depending upon the MHC class I of the recipient.

NK-cell reconstitution after allo-HCT

Reconstitution of immunity after allo-HCT can be influenced by a number of factors, including intensity of conditioning, hematopoietic cell source, graft manipulation, GVHD prophylaxis, and host factors (i.e., age and thymic function). NK cells typically recover within the first month after transplant and are therefore one of the first lymphocytes to recover after HCT, regardless of stem-cell source. Comparing the NK-cell reconstitution following reduced intensity or myeloablative conditioning, Peterson et al. found that NK cell reconstitution was rapid (by D+28) and not different [93]. Similarly rapid reconstitution has been reported for umbilical cord blood (UCB), bone marrow (BM), and haploidentical transplantation [94–96]. Regarding the function of NK cells recovering after transplantation, some have shown robust cytotoxicity [97], whereas others have found impaired killing and cytokine production [98,99]. Whether NK function early after transplant has any impact on transplant outcomes is currently unknown. One question was whether the recovering NK cells would have the same KIR repertoire as was present in the donor. This was addressed by Shilling et al. by following patients for up to 3 years after transplant [100]. Early after transplant, the majority of patients showed high expression of CD94/NKG2A and low amounts of KIR that slowly increased over time after bone marrow transplantation (BMT). Based on KIR acquisition, patients fell into three groups. The first group, which made up the majority of patients, recovered a KIR pattern similar to that of the donor within 6–9 months after transplant. A second group took longer (up to 3 years), but eventually showed a KIR distribution similar to that of the donor. The last group showed poor KIR acquisition and had multiple medical problems.

GVHD prophylaxis and treatment may also affect NK cell reconstitution and function. Vitale et al. studied the NK cells from transplant recipients before, during, and after steroid treatment for acute GVHD. They found a sharp decrease in cytoxicity, associated with a reduction in NKp30 and -46 [101]. Wang et al. cultured NK cells with physiological doses of cyclosporine (CSP) and found that it significantly inhibited the proliferation of CD56^{dim} NK cells and only marginally influenced CD56^{bright} cells [102]. After 1 week of culture in CSP, NK cells retained their cytotoxicity and their ability to secrete cytokines and were not different from controls. Such findings are interesting considering that CD56^{bright} cells predominate early after transplant [103–105], perhaps suggesting that CSP may play a role in phenotype and function of NK cells recovering early after transplant. Giebel et al. evaluated the number of NK cells in the peripheral blood of individuals at D+30 after transplant and showed that patients receiving prednisone for GVHD prophylaxis had fewer NK cells compared with those who did not receive prednisone. In contrast to prednisone-treated recipients, there was no difference in the number of NK cells in the peripheral blood of patients treated with or without antithymocyte globulin (ATG) [106], suggesting that prednisone may have more long-lasting effects on NK-cell recovery. Cooley et al. compared recipients of either T-cell-depleted or T-cell-replete transplants at D+100 with their donors and found that the percentage of NK cells did not differ. However at D+100, recipients of T-cell-replete transplants had more KIR and a higher percentage of IFN-γ-producing NK cells compared with T-cell-depleted recipients, suggesting that T cells within the graft influence NK-cell reconstitution [105]. Freud et al. also demonstrated that T cells could enhance NK-cell development from progenitor cells in vitro [79].

NK–DC interactions

DCs are professional antigen-presenting cells that are critically important in a number of immune responses. DCs exist in the circulation and peripheral tissues as immature (iDCs). Such cells are phagocytic, but poor at presenting peptide antigens to T cells. However, following activation, mature DCs (mDCs) are highly efficient at stimulating naïve T-cell responses. NK cells and DCs interact with one another both through soluble factors (i.e., cytokines) and via cell-to-cell contact.

NK–DC interaction, also known as "cross-talk," can result in a number of outcomes, including reciprocal activation of both cell types. Following co-culture with either immature or mature DCs (iDC or mDC), NK cells proliferate, express activation markers (CD25), acquire cytotoxicity, and produce IFN-γ and TNF-α [53,107]. This is driven by DC-derived cytokines including type I IFNs (α and β), IL-12, and IL-18 and by trans-presentation of IL-15 to NK cells via the IL-15α receptor on DCs [108–111]. The same conditions (NK:iDC co-culture) also lead to iDC maturation characterized by the acquisition of CD83 and CD86 and the ability to prime alloreactive T-cell responses [53,107,112]. NK-cell-induced maturation of DCs (and vice versa) occurs in part through the ligation of NKp30 (on NK cells) by its ligand (on DCs) [53,107]. Other studies showed that interactions between NKG2D on NK cells and MICA/B on DCs are also important for these interactions [112].

Paradoxically, NK cells can also kill DCs. The maturational status of DCs influences the sensitivity to NK-cell killing. Compared with mDCs, iDCs display relatively lower amounts of MHC class I on the cell surface and are more sensitive to NK-cell killing [53,107]. Higher amounts of MHC class I on mDCs result in a relative resistance to killing by autologous, but not allogeneic, NK cells. Killing of autologous mDCs by NK cells can be enhanced with blocking mAb against MHC class I, suggesting the involvement of KIR receptors [107]. Likewise, NK cells that express KIR receptors that cannot recognize MHC on the mDC show better cytotoxicity (i.e., KIR-L mismatched) [107]. Similarly to killing of tumor targets, the killing of DCs by NK cells is through NKp30, NKG2D, and DNAM-1

[53,107,112,113]. Communication between NK cells and DCs is potentially important in the setting of HCT, since recipient-derived DCs can present antigen to donor T cells and induce GVHD [114]. Studies using a murine model suggested that donor-derived NK cells can eradicate these recipient DCs and prevent GVHD [115].

NK cells, viral infections, and “NK memory”

Inherited deficiency and/or dysfunction of NK cells has been associated with severe and life-threatening viral infections, including infections with members of the herpes virus family, such as varicella zoster virus (VZV) [116,117], CMV [118], and Epstein–Barr virus (EBV) [119]. Similarly, humans with mutations in the perforin gene (in the case of hemophagocytic lymphohistiocytosis) result in fatal and uncontrolled viral infections. Following HCT, reactivation of herpes viruses also occurs and whether NK cells play a role in this process is not well defined. There is a clear association between the expression of NK-cell-activating protein Ly49H in certain mouse strains and the susceptibility to murine CMV [120]. Although NK cells have been described as innate immune cells that are devoid of immunological memory, recent studies by Lanier’s group have questioned this dogma by uncovering striking similarities between antigen specific T cells and NK cells that have previously been challenged by antigen. In particular, following mCMV infection, “memory-like” Ly49H$^+$ NK cells persist in mice. These cells rapidly respond to secondary mCMV challenge through proliferation and effector function, properties consistent with memory cells [121]. Following exposure to CMV in humans, a population of NK cells that express NKG2C emerges. Whether these are “memory NK cells” is not entirely clear, yet during acute infection, NKG2C$^+$ NK cells expand over 4 weeks and persist for the first year after transplantation [122]. These NK cells predominantly express self-KIR with robust IFNγ production after target cell exposure. However, this does not prove memory. In a second study, recipients of adult donor HCT were assessed to evaluate the role of donor/recipient CMV status on the expression and function of NKG2C$^+$ NK cells in order to determine responses to secondary CMV events. Expansion of NKG2C$^+$ NK cells was seen with clinical CMV reactivation, as expected. In addition, they also expanded in the absence of detectable CMV viremia when both the donor and recipient were CMV seropositive. Upregulation of NKG2C was detected on NK cells from CMV-seropositive recipients receiving grafts from CMV-seropositive donors. These in vivo-expanded NKG2C$^+$ NK cells were highly functional. In conclusion, the enhanced secondary exposure is consistent with NK-cell memory and shows that they are transplantable.

Clinical studies

Allogeneic HCT functions through both conditioning therapy (chemotherapy and irradiation) and an immune-mediated eradication of resistant leukemia cells. This latter point, referred to as graft-versus-leukemia (GVL), is mediated via the actions of alloreactive T cells and NK cells. NK-cell alloreactivity has attracted considerable attention over the past decade, in part due to observations that allogeneic NK cells can induce GVL without GVHD [115,123]. Considering the importance of HLA matching in HCT and the fact that each KIR receptor recognizes specific allelic determinants of HLA, such interactions are likely to be important in GVL reactions. However, such interactions are complex and not entirely understood. For instance, the expression of KIR on individual NK cells occurs through a stochastic process with each NK cell expressing a varying number of KIR receptors of differing MHC class I specificity [27]. Thus, contained within the circulation of all potential donors is a heterogeneous pool of NK cells (with regard to KIR expression, see Figure 11.2) and in any individual only a minority of these cells may have alloreactive capacity (i.e., are unrestrained by KIR–MHC interactions).

The observation that NK-cell alloreactivity is important in GVL was established by the Perugia group in the context of T-cell-depleted and CD34-selected haploidentical transplantation [115,124]. In these transplants, donors (parents or siblings) share one haplotype with the recipient, but are also mismatched at the other haplotype. This creates a situation where alloreactivity is possible, especially if donor NK cells express KIR that cannot recognize MHC on recipient leukemia cells, fulfilling the “missing self” hypothesis. As shown in Figure 11.4, following haploidentical transplantation three possible outcomes could occur: (1) NK-cell alloreactivity in the graft-versus-host direction, which would favor GVL reactions, (2) NK alloreactivity in the host-versus-graft vector, which could favor rejection, or (3) no alloreactivity owing to compatibility between the donor and recipient with respect to HLA epitopes.

In general, alloreactions between NK cells expressing receptors for HLA-C appear to be dominant over those for HLA-B [125]. This is perhaps due to the higher number of HLA-C-specific KIR receptors and possibly their greater affinity for ligand. Consequently, in the original report addressing NK cell alloreactivity after transplant, Ruggeri et al. found that the majority of alloreactive NK cell clones generated after haploidentical transplantation were reactive to differences in HLA-C [124]. Such clones could be detected in

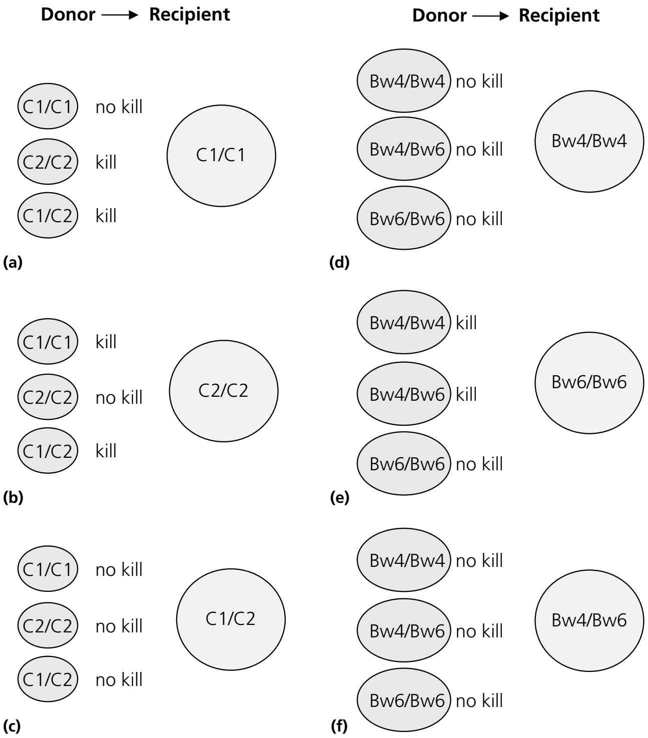

Figure 11.4 Potential outcomes following transplants depending upon donor and recipient KIR-L compatibility. Shown are the possible outcomes depending upon donor and recipient HLA-C dimorphisms (C1/2) [(a)–(c)] and HLA-B dimorphisms(Bw4/Bw6) [(d)–(f)]. Source: adapted from Wit and Christiansen 2006 [144].

patients for up to 1–3 months after transplantation. Following KIR-L mismatched transplants (see below), these anti-recipient NK cell clones could be detected in all patients, whereas they were essentially absent in KIR-L-matched transplant recipients [115]. AML patients transplanted with a KIR-L mismatched donor showed a low probability of relapse at 5 years. In contrast, a similar population of AML patients transplanted in the same manner with a KIR-L-matched donor poor showed poor outcomes, with 75% relapsing by 5 years [115]. Importantly, the effect of KIR-L mismatching was restricted to patients with myeloid leukemia and no relapse or survival benefit was observed for ALL patients transplanted with a KIR-L-mismatched donor. An updated analysis by the Perugia group showed that patients with chemotherapy relapses did not benefit from KIR-L-mismatched donors [126].

The above observations on NK alloreactivity have been referred to as the "ligand–ligand" model, where prediction of NK-cell alloreactivity is based on the presence or absence of MHC class I alleles (HLA-B or-C) in the recipient relative to the donor (i.e., whether the donor and recipient express the same or different HLA-Bw4 or HLA-C1/C2 alleles). Thus, KIR ligand mismatch analysis using the ligand–ligand model can be viewed as an analysis of donor-versus-recipient epitope similarity in the GVH direction for HLA-B and -C alleles. Determination of KIR-L mismatch status using this model can be performed using an online tool, available at http://www.ebi.ac.uk/ipd/kir/ligand.html. However, this approach may be limited since it assumes that a particular donor expresses KIR receptors for the corresponding ligand. It is well established that individuals differ in the number of KIR genes contained in their genome, hence not all individuals will express all KIR receptors [27]. Leung and co-workers took into account whether donors and recipients differ with respect to HLA-B and -C alleles, but also determined whether the donor expressed the KIR receptor for the mismatched HLA class I allele (i.e. KIR-L). They found that using their "receptor–ligand" model, patients with both AML and ALL experienced lower leukemia relapse rates if transplanted with a KIR-L-mismatched donor who expressed the appropriate KIR [127,128].

Importantly, not all investigators have been able to demonstrate a benefit for AML patients undergoing haploidentical transplantation using KIR-L-mismatched donors. Nguyen et al. transplanted 10 AML patients with a haploidentical donor (8/10 being KIR-L mismatched) using the same regimen and peripheral blood progenitor cell (PBPC) selection techniques as in the above studies. However, unlike in the above studies, they found that all patients died due to either relapse (7/10) or infection (3/10) [99]. The authors demonstrated that NK cells recovering after this procedure were immature in both phenotype and function and speculated that this might account for their clinical observations.

Whether KIR-L mismatching affects outcomes in the setting of unrelated donor transplantation has been the subject of numerous retrospective studies, with mixed results. Initially, a large registry analysis by Davies et al. showed that a KIR-L-mismatched donor had no impact on the incidence of AML relapse following T-cell-replete transplantation [129]. Shortly afterwards, Giebel et al. showed a protective effect of KIR-L mismatch for AML patients in the unrelated donor setting [130]. Interestingly, this latter study used ATG for in vivo T-cell depletion (TCD), leading to the speculation that T cells might influence NK alloreactivity. Similar results were obtained by Hsu et al. in a TCD-matched sibling cohort [131].

The use of KIR-L-mismatched donors may also affect transplant-related outcomes other than relapse. For instance, Schaffer et al. found an increase in treatment-related mortality (TRM) in KIR-L=mismatched recipients due to a higher rate of infectious complications [132]. Similarly, Kroger et al. found that KIR-L-mismatched recipients had a higher rate of TRM [133]. Examining HLA-C mismatch, De Santis et al. found that in donors and recipients who were mismatched for C1 and C2 epitopes, there was more grade II–IV GVHD if the mismatch was in the GVH vector [134]. Conversely, if the mismatch was in the rejection vector (HVG), more rejection was observed. Regardless of the vector, these investigators found that KIR-L mismatching was associated with inferior outcomes and increased TRM [134]. However, analyzing a large data set (n = 1571), Farag et al. were not able to demonstrate any impact of non-relapse mortality in KIR-L-mismatched transplants in either vector [135]. Clearly, differences in hematopoietic cell source, conditioning regimen, and GVHD prophylaxis may affect such observations.

In addition to KIR-L mismatching, some investigators have analyzed data sets based on the presence or absence of a specific KIR or the quantity of KIR receptors expressed by the donor. In the setting of fully HLA-matched transplant (HLA 8/8), KIR-L mismatch cannot occur; however, transplant recipients whose donor expressed both KIR2DS1 and KIR2DS2 had better outcomes due to a reduction in leukemia relapse [136]. In a large National Marrow Donor Program (NMDP) study, Cooley et al. showed that donors with an increase in activating KIR had lower relapse and improved disease-free survival for myeloid leukemia patients [29]. Chen et al. found that more activating KIR in the matched related donors resulted in lower TRM and better overall survival (OS) [137]. An increase in the total number of KIRs (both activating and inhibitory) contained within the donor was associated with a reduction in GVHD and an improved OS [134].

Adoptive NK-cell transfer for refractory leukemia and cancer

Another way to promote antitumor activity with alloreactive NK cells is through NK-cell adoptive transfer. This can be achieved using several strategies. One approach is based on ex vivo NK cell expansion using supraphysiologic concentrations of cytokines (i.e., high-dose IL-2]. The safety and success of this approach were established in a trial using haploidentical, related-donor NK cells that were activated overnight in IL-2 and infused into 43 patients with metastatic melanoma, metastatic renal cell carcinoma, refractory Hodgkin disease, or AML [123]. The trial, which tested three preparative chemotherapy regimens of differing intensity, confirmed that successful NK-cell expansion was see only n in the cohort who received the fully lymphodepleting chemotherapy consisting of cyclophosphamide (60 mg/kg) days –4 and –5 and daily intravenous fludarabine (25 mg/m^2) days –5 to –1. NK cells were infused on day 0, followed by six doses of subcutaneous IL-2 (10 million units) over 2 weeks. Following the lymphodepleting chemotherapy, a surge of endogenous IL-15 was observed over the first 28 days after chemotherapy. A significant inverse correlation was seen between the IL-15 levels and the absolute lymphocyte count, and high levels correlated with successful NK-cell expansion, supporting the importance of IL-15 for NK cell homeostasis. Of the 19 patients with poor-prognosis AML, five achieved complete remissions. The remission patients had significantly higher proportions of circulating NK cells which were significantly more cytotoxic against K562 targets, suggesting that clinical efficacy was mediated by the in vivo-expanded allogeneic donor NK cells. The presence of haploidentical NK cells in the circulation is transient and we speculate that these cells are likely rejected by recipient T cells. To overcome this hurdle, some investigators are now planning clinical trials with NK cells that have been expanded long term with engineered feeder cells or EBV lymphoblastoid cell lines that lead to NK-cell expansion. However, concern has been raised in both short- and long-term culture conditions where removal of the NK cells from the high-dose cytokine culture media may lead to cell death. In addition, upon activation, NK cells undergo marked changes in size and adhesion receptor expression, which may alter homing characteristics in vivo.

In addition, the use of post-infusional IL-2 also has the potential to stimulate regulatory T cells which express high levels of IL-2Rα (CD25). These regulatory T cells can impair NK-cell function and perhaps expansion [138]. To overcome this, IL-15 may be optimal to promote adoptive transfer of allogeneic NK cells because it has a minimal effect of regulatory T-cell activation.

Conclusion

NK cells recover early after transplantation. These cells kill malignant cells without prior priming, using a limited number of pattern recognition receptors that detect cells undergoing stress. By understanding these receptors and their ligands, an understanding of how NK cells function to mediate GVL after allo-HCT is emerging. However, there is still an incomplete understanding of both the receptors that they use and the ways to maximally activate NK cells. At present, there are several limitations to the therapeutic potential of adoptively transferred allogeneic NK cells. The NK-cell yield from lymphopheresis collections is limited. Although NK cells can be successfully expanded in vivo, the success is unpredictable and the expanded cell population is transient. Additionally, the homing signals required to direct NK cells to tumor sites are not fully understood. Furthermore, the alloreactivity of in vivo expanded NK-cell populations may be heterogeneous due to variable KIR repertoire expression or to differences in NK cell or accessory cell subsets. The use of mAbs that block NK-cell inhibitory receptors may increase antitumor killing [139], and more sophisticated techniques for subset selection in NK-cell products may affect the interaction between the innate and adaptive immune responses, for example by removing any regulatory T cells that can suppress NK-cell proliferation and killing, and may also improve the immune effector functions of the expanding NK cells [140]. NK-cell expansion may be improved by refining the use of lymphodepleting chemotherapy or the use of concurrent exogenous cytokine therapy. Irradiated cell lines such as NK-92, KHYG-1 and embryonic stem-cell-derived NK cells may provide an inexhaustible supply of NK cells, but the in vivo homing and survival are not well known [141,142]. Ex vivo expanded cells from any source can be genetically modified to express tumor-specific receptors. For example, the NK-92 cell line has been transfected with a chimeric antigen receptor for HER2/neu, which conferred superior cytotoxicity against HER2/neu positive targets [142]. Lastly, the antitumor activity of NK cells depends not only on the KIR ligand mismatch status, but also on tumor expression of appropriate activating ligands. Future strategies to enhance activating ligand expression on tumor cells may increase their susceptibility to NK-cell-mediated lysis. Other avenues of research for NK-cell immunotherapy include engineering NK cells with transferred genes, incorporating NK cells into DC vaccine therapies, and combination therapy with immunomodulatory drugs such as thalidomide, Toll-like receptor agonists, and mAbs to target ADCC.

CHAPTER 12

Mechanisms of Tolerance

Introduction

In classical experiments, Medawar and co-workers injected neonatal mice of one strain with lymphoid tissue cells from another. After the recipient mice grew to adulthood, they permanently accepted skin grafts from the donor strain but rejected the skin grafts from a third-party strain; this phenomenon was called "actively acquired tolerance of foreign cells" [1]. In order to apply this approach to adult instead of neonatal mouse recipients, approximately 20 years later, investigators at Stanford University developed the first non-myeloablative regimen (total lymphoid irradiation, TLI) that resulted in permanent acceptance of combined bone marrow (BM) and skin transplants associated with the development of stable mixed chimerism and without graft-versus-host disease (GVHD) [2]. Prior studies of BM transplantation in mice used total body irradiation (TBI) to condition recipients, and engraftment was almost always associated with the development of GVHD when multiple minor histocompatibility antigens or single major histocompatibility antigens differed between hosts and donors [3]. Transplantation immune tolerance is now defined as a physiological state, in which the immune system does not launch a destructive response against an allogeneic organ or tissue graft. It is now known that the destructive response is mediated by alloreactive TCR$\alpha\beta^+$ T cells, B cells, NK cells, and a variety of other cells, but T cells play a dominant role. This chapter focuses on mechanisms that tolerize alloreactive TCR$\alpha\beta^+$ T cells that mediate host-versus-graft (HVG) responses in organ transplantation and graft-versus-host (GVH) responses in hematopoietic cell transplantation (HCT); the former causes graft rejection and the latter can cause GVHD.

General mechanisms of alloreactive T-cell immune tolerance

Alloreactive T cells include both mature T cells that are in the peripheral lymphoid tissues before transplantation and newly developed T cells derived from hematopoietic stem and progenitor cells after transplantation. Induction of tolerance among the developing T cells in the thymus after encounter with antigens in the thymus is defined as central tolerance. Induction of tolerance among mature T cells that encounter antigen in the peripheral lymphoid tissues is called peripheral tolerance. The general mechanisms of T-cell tolerance include clonal deletion, ignorance, anergy, exhaustion, and suppression. These mechanisms can involve both central and peripheral tolerance, with clonal deletion being the major mechanism in central tolerance, and anergy, exhaustion, and suppression being the major mechanisms in peripheral tolerance.

Clonal deletion

Burnet theorized that immature T cells encountering their antigen during development are clonally deleted instead of being activated [4]. This theory was confirmed by Kappler and co-workers by showing that the T-cell subset expressing the Vβ17a$^+$ T-cell receptor (TCR) accounted for about 10% of T cells in mice that did not express an I-E molecule. In contrast, mice that express I-E molecules had a marked reduction of the Vβ17a$^+$ cells. When I-E$^+$ and I-E$^-$ strains were crossed, the F1 offspring contained few Vβ17a$^+$ cells in the periphery; this dominant elimination process was found to take place in the thymus. The deletion of T-cell clones with the Vβ-specific TCR was found to be mediated by mouse mammary tumor virus (Mtvs) superantigen, which activates T cells by interacting with both the Vβ17a TCR and the I-E molecule at the same time [5]. The deletion of immature autoreactive thymocytes was also demonstrated by transgenic T cells specific for H-Y antigens; these T cells were markedly reduced in the thymus of male mice [6]. Hence clonal deletion is a major mechanism of central tolerance via thymic negative selection.

Thymic clonal deletion of immature T cells is predominantly mediated by hematopoietic cell-derived antigen-presenting cells (APCs) [e.g., CD11c$^+$ dendritic cells (DCs) and B1 B cells] in the thymus, especially DCs [7]. Thymic medullar epithelial cells can mediate deletion of T cells that recognize tissue-specific antigens, and this process is often regulated by the autoimmune regulator (AIRE) protein [8]. Thymic DC-mediated clonal deletion usually takes place at the junction of cortex and medulla, but it can also take place in the cortex [9]. Circulating activated T cells and DCs carrying peripheral tissue-specific antigens can also enter the thymus to mediate clonal deletion [10,11].

Thymic clonal deletion takes place when the avidity of immature T-cell interaction with APC is high; the avidity is influenced by variations of TCR affinity and density, antigen–major histocompatibility complex (MHC) complex density, and the expression of costimulatory molecules by APCs. Higher avidity and costimulatory signaling augment clonal deletion [12]. Transgenic autoreactive T cells are often deleted at the transitional stage between CD4$^-$CD8$^-$ and CD4$^+$CD8$^+$ during thymocyte development; non-transgenic T cells are usually deleted at late stage of CD4$^+$CD8$^+$ thymocyte development in the cortex and the junction of cortex and medulla [9]. Early CD24^{hi}CD4$^+$CD8$^-$ T cells can be deleted in the

medulla by interaction with APCs that express costimulatory molecules such as CD40 and B7 [13].

The activation threshold for thymic deletion is much lower than that for peripheral T-cell activation, hence the autoreactive T cells that escape from thymic deletion are usually not activated by low-avidity interacting ligands in the periphery [14]. However, clonal deletion is not only limited to immature thymocytes, since mature T cells in the periphery can also undergo clonal deletion through activation -induced cell death [15]. Mature donor reactive T cells in the periphery undergo clonal deletion early after HCT in the presence of costimulatory blockade (anti-CD40L and CTLA-4-Ig) [16]. Donor-type APCs in mixed chimeras given MHC-matched or -mismatched donor BM transplants mediate thymic deletion of donor reactive T cells and provide immune tolerance to donor-type tissue and organ transplants [17]. GVHD causes damage to the thymus, which may result in defective thymic deletion of host-reactive T cells and development of chronic GVHD [18,19].

Even under normal thymic negative selection, clonal deletion of autoreactive T cells in normal individuals or alloreactive T cells in HCT recipients in the thymus is rarely complete, and some of the auto- or alloreactive T cells can be exported into the peripheral lymphoid tissues. There, they are controlled by peripheral tolerance mechanisms, including ignorance, anergy, exhaustion, and suppression.

Ignorance

Immune ignorance is referred to as a state in which auto- or alloreactive T cells in the lymphoid tissues are not activated, because antigen levels are below the threshold level required for activation of T cells. For example, autoantigens from tumor cells can be too low to activate the antigen-specific T cells in the draining lymph nodes [20]. Allografts without contaminating passenger leukocytes allow alloantigens to stay outside organized lymphatic tissues, and can avoid immune rejection [21].

Anergy

T-cell anergy is a state in which T cells intrinsically become functionally inactivated following an antigen encounter, but remain alive for an extended period as hyporesponsive T cells [22]. The basic types of T-cell anergy fall into two categories: T-cell clonal anergy and adaptive tolerance. The former is usually induced in vitro and is principally a growth arrest state arising from incomplete T-cell activation; the latter is also known as in vivo anergy, resulting from the challenge of T cells in the periphery by APCs presenting superantigen or specific peptides in the absence of costimulatory signaling [22]. T-cell clonal anergy and adaptive tolerance have many common and distinguished features: both involve CD4$^+$ and CD8$^+$ T cells; both show little IL-2 production and hyporesponsiveness; and both can be reversed by anti-OX40 mAb (monoclonal antibody) treatment. However, although T-cell clonal anergy shows inhibition of proliferation, it does not show reduction of effector function such as production of IL-4 and IFN-γ and also cytotoxicity activity. In contrast, T-cell adaptive tolerance not only shows inhibition of proliferation but also shows reduction in IL-4 and IFN-γ production and cytotoxicity activity. Although T-cell clonal anergy does not downregulate IL-2R and can be reversed by exogenous IL-2, T-cell adaptive tolerance does block IL-2R signaling and exogenous IL-2 cannot reverse it. Finally, CTLA-4 signaling is involved in T-cell adaptive tolerance but not T-cell clonal anergy; persistence of antigen is required for maintenance of T-cell adaptive tolerance but not clonal anergy [22].

T-cell anergy is usually induced by TCR stimulation (signal 1) without concomitant CD28 and IL-2R signaling (signal 2). In the absence of signal 2, TCR signaling leads to activation of calcium influx and nuclear factor of activated T cells (NFAT), and induces a cascade of anergy proteins, including the E3 ubiquitin ligases Cbl-b, Itch, and Grail, which target proximal TCR signaling molecules for degradation [23]. Signal 2 leads to activation of the PI3–AKT–mTOR pathway and IL-2 production, which can reverse T-cell anergy [24]. Anergic T cells are blocked at the G1/S checkpoint of the cell cycle and in a metabolically anergic state characterized by a failure to upregulate nutrient transporters, such as CD71, CD98, and Glut1 [25]. Activation of the AKT–mTOR pathway is also critically required to induce a switch in the T-cell metabolic machinery from catabolism to anabolism, through stimulation of glycolysis and upregulation of key nutrient transporters [26]. This establishes the basis for the optimal activation, proliferation, and differentiation of T cells. This T-cell activation and anergy switch can also be regulated by AKT–mTOR independent pathways. Plasmacytoid DCs that express indoleamine 2,3-dioxygenase (IDO) activate the GCN2 kinase in responding T cells and mediate the T-cell anergy [27]. Additionally, TCR signaling alone has been shown to upregulate A2A adenosine receptors on T cells, and A2A receptor interaction with tissue-derived adenosine can inhibit activation of the Ras–Map–kinase pathway and result in T-cell anergy [28].

T-cell anergy is generally involved in peripheral tolerance, and donor-specific unresponsiveness has been shown in animal models and patients with organ transplantation immune tolerance, but the role of T-cell anergy in transplantation tolerance is not easily distinguished from clonal deletion, because both can result in lack of alloreactivity in the mixed lymphocyte reaction (MLR) assay. Treatment with calcineurin inhibitors (e.g., cyclosporine and tacrolimus) that block the calcineurin–NFAT pathway and the induction of T-cell anergy can prevent the induction of transplantation tolerance; in contrast, treatment with mTOR inhibitors (e.g., sirolimus) that block the PI3–AKT–mTOR pathway and augment the induction of T-cell anergy can facilitate the induction of transplantation immune tolerance [29]. Additionally, "infectious tolerance" is found to be associated with induction of anergy of alloreactive T cells by regulatory T (Treg) cells [30]. The latter finding suggests that T-cell anergy contributes importantly to transplantation immune tolerance.

Exhaustion

T-cell exhaustion is a state of T-cell dysfunction defined by (1) poor effector function such as marked reduction in production of cytokines (e.g., IFN-γ, TNF-α, IL-2) and cytotoxicity and (2) upregulation of expression of inhibitory receptors such as PD-1 and Tim-3 [31]. T-cell exhaustion usually arises in the case of chronic infection and cancer [31]. T-cell exhaustion differs from T-cell anergy in the following respects. (1) Although both can be hyporesponsive, T-cell anergy is induced at the time of first antigen stimulation and is initiated rapidly owing to lack of costimulation; but T-cell exhaustion takes place after full T-cell activation with costimulation. T-cell exhaustion is progressive, with dysfunction worsening over time. (2) Although NFAT has a role in both situations, anergy-associated genes such as Grail do not seem to be upregulated in exhausted T cells; instead, Blimp that controls the terminal differentiation of cells is overexpressed by exhausted T cells. The latter is associated with upregulated expression of many inhibitory receptors such as PD-1, Tim-3, LAG3 (CD160), and CD244 (2B4). (3) Antigen persistence is required for maintaining but not inducing anergy, but is required for inducing exhaustion. (4) Although both anergy and exhaustion involve CD4$^+$ and CD8$^+$ T cells, anergy is better studied with CD4$^+$ T cells and exhaustion is better studied with CD8$^+$ T cells [31].

The contribution of T-cell exhaustion to organ transplantation immune tolerance is unclear. The conditioning regimen of TLI that induced tolerance to combined organ and BM transplants has been shown to induce the PD-1$^+$Tim-3$^+$ exhausted phenotype among host CD8$^+$ T cells [32]. The latter host cells are unable to reject the donor marrow cells that establish chimerism and clonal deletion. In addition, alloreactive CD8$^+$ T-cell exhaustion and loss of graft-versus-tumor (GVT) effect was reported to be mediated by antigen presentation by non-hematopoietic cells in HCT recipients [33]. In vivo OX40 ligation was reported to expand CD4$^+$Foxp3$^+$ Treg cells but led to downregulated expression of Foxp3 and exhaustion of the Treg cells [34].

Suppression

Studies in the early 1980s by Strober and co-workers showed that naturally occurring immune suppressor cells existed in the neonatal spleen and adult BM of mice and rats, and that suppressor T cells contributed to allograft tolerance in recipients treated with TLI [35]. Hall et al. also showed that suppressor T cells existed in the rat recipients of cardiac allografts after cyclosporine treatment, and the suppressor T cells contributed to the long-term survival of the grafts in the absence of continuous cyclosporine therapy [36]. In the mid-1990s, Sakaguchi and co-workers found that CD25$^+$CD4$^+$ T cells regulated tissue-specific autoimmune diseases [37], and subsequently that CD25$^+$CD4$^+$ Treg cells express Foxp3 [38]. Despite the skepticism that once prevailed among immunologists, it is now widely accepted that the normal immune system harbors a variety of naturally occurring immune-regulatory cells that target a wide variety of antigenic specificities. In addition to Foxp3$^+$CD25$^+$CD4$^+$ Treg cells, there are other CD4$^+$ and CD8$^+$ Treg cells and also regulatory B (Breg) cells, dendritic cells, and myeloid cells [39]. Below is a summary of major immune suppressor cells.

CD4$^+$CD25$^+$Foxp3$^+$ Treg cells

CD4$^+$CD25$^+$Foxp3$^+$ Treg cells can be divided into natural (nTreg) cells that develop in the thymus and induced (iTreg) cells that derive from mature CD4$^+$ T cells in the peripheral lymphoid tissues during T-cell activation and differentiation. It is proposed that thymocytes with intermediate TCR avidity for autoantigens presented by thymic stromal cells are activated to express Foxp3, and become Foxp3$^+$ nTreg cells; thymocytes with low avidity for autoantigens become Foxp3$^-$ conventional T cells; and the thymocytes with high avidity TCR for autoantigens are negatively selected [40]. nTreg cells are positively selected in thymic medulla instead of cortex at the HSA^{hi}CD4$^+$ single positive stage instead of CD4$^+$CD8$^+$ double positive stage. Either thymic medullar epithelial cells or medullar hematopoietic cell-derived APCs are sufficient to mediate the positive selection, although it is unclear whether the different APCs select different nTreg cells with different antigen specificity. Intrinsic factors such as TCR signaling and costimulatory signaling mediated by CD28 and also extrinsic factors such as cytokines (e.g., IL-2 and IL-15) regulate the selection. CD28 deficiency results in defective nTreg cell development [41].

A majority of Foxp3$^+$CD4$^+$ Treg cells in the periphery are nTreg cells, and nTreg-cell survival in the periphery requires presence of self-antigens, but there are also iTreg cells that derive from conventional CD4$^+$ T cells during T-cell activation and differentiation in the secondary lymphoid organs or inflamed tissues [42,43]. During in vitro culture, in the presence of TGF-β or retinoic acid (RA), conventional T cells upregulate Foxp3 expression and become iTreg cells [44,45]. This differentiation can be shifted to Th17 by the presence of IL-6 and IL-1 [45]. In vivo, conventional T cells can differentiate into iTreg cells in a tolerogenic microenvironment such as the mucosa of the small intestine and also during acute and chronic inflammation, but iTreg cells are generated at a much lower rate than T effector cells [46]. The use of non-depleting anti-CD4 monoclonal antibodies (mAbs) that weaken coreceptor engagement and blockade of PI3–AKT–mTOR led to the generation of iTreg cells [47,48]. The common feature of nTreg and iTreg cells is the expression of one or more anti-inflammatory molecules, such as IL-10, TGF-β, or IL-35, and/or inhibitory molecules, such as CTLA-4, LAG-3, GITR, CD39, or CD73. Although in vivo-generated iTreg and thymic-generated nTreg cells have similar gene expression profiles, nTreg cells tend to have higher expression of Gzmb (granzyme B), Ikzf2 (helio), and Nrp1 (neuropillin-1) genes, and iTreg cells have higher expression of Il10 (IL-10), Ctla4 (CTLA-4), Ebi3 (a component of IL-35), and Klrg1 genes [46].

Treg cells downregulate T-cell homeostatic expansion, autoimmunity, and alloimmunity through several mechanisms, including the following. (1) Consumption of IL-2: Treg cells that express CD25 IL-2Rα with high affinity to IL-2 are more efficient than naïve or effector T cells in capturing IL-2 [49]. (2) Treg cells that express high levels of CTLA-4 that has a higher affinity than CD28 for CD80 and CD86, in particular CD80. Treg CTLA-4 interacts with APCs (e.g., DCs) with greater avidity than conventional T cells, and the interaction also activates IDO-dependent catabolism of tryptophan to immunosuppressive kynurenine in DCs, which can induce DC apoptosis or induce DC into a tolerogenic state that anergizes naïve T cells. This interaction can also activate Foxp3 in DCs and subsequently downregulate DC production of IL-6. CTLA-4 on Treg cells can also induce endocytosis and trogocytosis of CD80 and CD86 from APCs [50]. (3) Treg cells can secrete suppressive cytokines such as TGF-β, IL-10, and IL-35, and can directly kill target lymphocytes via granzyme B [51,52]. (4) nTreg and iTreg cells working together can produce optimal immune suppression. For example, in an autoimmune colitis model, full rescue of mice could be obtained only if the naïve T-cell population had been obtained from wild-type but not Foxp3-deficient mice that could generate in vivo Foxp3 iTreg cells [43].

CD8$^+$Foxp3$^+$ Treg cells

Several types of CD8$^+$ regulatory T cells have been reported in recent years, including (1) CD8$^+$CD28$^-$ T cells that were identified in a mouse experimental autoimmune encephalomyelitis (EAE) and renal transplantation patients after alemtuzumab (anti-CD52) treatment [53,54]; (2) CD8$^+$ IL-10-producing T cells identified in a renal transplantation patient with long-term graft acceptance on immunosuppressive drugs [55]; (3) FOXp3$^-$CD8$^+$122$^+$CXCR3$^+$ T cells identified in autoimmune diabetic NOD mice [56]; and (4) Foxp3$^+$CD8$^+$ T cells that were identified in systemic lupus mice after tolerogenic treatment with consensus peptide [57] and in lupus patients after autologous HCT [58], and also in multiple sclerosis patients [59].

Foxp3$^+$CD8$^+$ T cells were reported to share developmental and phenotypic features with classical CD4$^+$Foxp3$^+$ Treg cells; the Foxp3$^+$CD8$^+$ T cells can arise naturally in the thymus, although the percentage among CD8$^+$CD4$^-$ thymocytes is much lower than that of Foxp3$^+$CD4$^+$ T cells. The Foxp3$^+$CD8$^+$ T cells can be

CD28$^+$ or CD28$^-$, and express high levels of CTLA-4, CD25, GITR, and CD103 [60]. The Foxp3$^+$CD8$^+$ T cells can be converted from conventional CD8$^+$ T cells in mesenteric lymph nodes or in vitro culture with IL-2, TGF-β, and RA; the conversion was augmented by blockade of the AKT–mTOR pathway. They can suppress autoimmunity and alloimmunity in a cell–cell contact manner, kill activated T and B cells, and prevent lupus, allograft rejection, and GVHD [61–63].

Natural killer (NK) T cells

Differing from conventional T cells that recognize peptide antigens presented by polymorphic antigen-presenting molecules, MHC I and II, NKT cells recognize lipid antigens presented by the non-polymorphic antigen-presenting molecule CD1d. Thus, NKT cells represent a family of developmentally and functionally distinct T- cell subsets. NKT cells produce large amounts of Th1 (i.e., IFN-γ), Th2 (i.e., IL-4), and Th17 (i.e., IL-17) cytokines hours after TCR engagement, which can either promote cell-mediated immunity against tumor and infection organisms or suppress autoimmunity and alloimmunity [64]. NKT cells can be divided into type I and II subsets. Type I NKT cells express the invariant TCR α chain (Vα14Jα18 in mice and Vα24Jα18 in humans) coupled with a TCR β chain of limited diversity, including Vβ8.2, -7 and -2 in mice and Vβ11 in humans [64]. Type I NKT cells include subsets that are CD4$^+$ or CD4$^-$CD8$^-$ in mouse and CD4$^+$, CD8$^+$, or CD4$^-$CD8$^-$ in humans. Type I NKT cells recognize the prototypical lipid antigen glycosphingolipid α-galactosylceramide (α-GalCer); they also recognize bacterial glycolipids (e.g., α-galacturonosylceramide), and mammalian glycolipids such as isoglobotrihexosylceramide (iGb3) [64]. Type I NKT cells can be identified by staining with CD1d-αGalCer tetramer [64]. Type II NKT cells usually express diverse TCRαβ, but some subsets have a biased repertoire such as Vα3.2 or Vα8 coupled with Jα9 or Vβ8. Type II NKT cells are often CD4$^+$ or CD4$^-$CD8$^-$, and recognize sulfatide, lysophosphatidylcholine, or non-lipid small aromatic molecules [65]. They can be identified with sulfatide-loaded CD1d tetramers [65].

Studies of NKT development mainly concerned the type I invariant subset. NKT cells develop in the thymus and diverge from conventional T cells at the CD4$^+$CD8$^+$ thymocyte stage, and they are positively selected by CD1 expressed on CD4$^+$CD8$^+$ thymocytes [64]. The negative selection of NKT is not yet clear, but NKT development is abrogated by the presence of dendritic cells that transgenically overexpress CD1d, suggesting that DC may mediate its negative selection. Thymic differentiation of NKT cells involves stages of selection, proliferation, and maturation, which include three stages; stages 1 and 2 takes place in the thymus, and stage 3 is continued in the periphery [66]. The differentiation process is associated with changes of surface marker and cytokine profile. Thus, NKT cells exhibit "'memory at birth," meaning that they acquire an antigen-experienced CD44^{hi} phenotype in the mouse thymus [66].

The simultaneous production of Th1, Th2, and Th17 cytokines by NKT cells is probably due to the existence of functionally distinct subsets. For example, human type I CD4$^+$ NKT subset produces both Th1 and Th2 cytokines in vitro, whereas type I CD8$^+$ or CD4$^-$CD8$^-$ NKT cells produce mainly Th1 cytokines in vitro [65]. NK1.1$^-$ and NK1.1$^+$ type 1 NKT subsets in mouse thymus have striking differences in cytokine profile. Whereas the NK1.1$^-$ subset produce large amounts of IL-4 with little IFN-γ, the NK1.1$^+$ subset produce large amounts of IFN-γ, with small amounts of IL-4 [65]. A subset of CD4$^+$ NKT cells that express IL-25 receptor produced large amounts of IL-4 and IL-13 yet little IFN-γ in response to IL-25 stimulation [65]. Another subset of type I NKT cells is called NKT-17; they are αGalcer-tetramer$^+$NK1.1$^-$CD4$^-$; they express the nuclear transcription factor RoRγt and produce large amounts of IL-17 [65].

The paradoxical role of NKT cells in promoting and suppressing immune responses is also probably due to different NKT subsets. For example, IL-25R$^+$ but not IL-25R$^-$ type 1 NKT cells were found to mediate allergic tissue damage [67]. Type I NKT cells augmented but type II NKT cells suppressed tumor immune surveillance [68]. In addition, type II NKT cells mediated anergy of type I NKT cells and prevented inflammatory liver diseases [68]. Abnormal cytokine profiles of NKT cells were associated with type 1 diabetes and systemic lupus [69,70]. Prevention of allograft rejection and prevention of GVHD was associated with NKT cell production of IL-4 [32,71]. In humans, NKT cell levels in donor BM transplants or in donor chimeric cells in the early recovery phase after HCT are powerful predictors of acute GVHD [72].

Regulatory B cells

Although B cells play a central role in humoral immunity and also in APC function that amplifies cellular autoimmunity and chronic GVHD [73–75], the existence of B cells with a suppressive capacity was initially reported in the 1970s, since B-cell-depleted splenocytes were unable to inhibit delayed-type hypersensitivity (DTH) skin reactions in guinea pigs [76]. Subsequently, in the early 1980s, it was reported that suppressive B cells were associated with induction of antigen-specific T suppressor cells in mice [77]. It was then convincingly demonstrated, in 2002, that Breg cells that produce IL-10 and upregulate expression of CD1d can suppress chronic intestinal inflammation [78]. Currently, Breg cells have been shown to downregulate autoimmunity in a variety of autoimmune diseases in mouse models and humans such as EAE, collagen-induced arthritis (CIA), colitis, and systemic lupus [79]. Breg cells also suppress antitumor immunity, augment induction of organ transplantation immune tolerance, and prevent GVHD [79].

The origin of Breg cells is not yet clear. Although some data suggest that Breg cells develop from naïve follicular B cells, other data indicate that Breg cells arise from a common progenitor that give rise to marginal zone (MZ) and T2 transitional B cells [79]. In addition to the production of IL-10, Breg cells generally have the MZ-T2 B-cell surface phenotype of CD19$^+$CD5$^+$CD1^{hi}CD21^{hi}CD23^{hi} [79]. More recently, they have been identified as CD19$^+$TIM-1$^+$, because ~70% of IL-10-producing B cells are TIM-1$^+$; TIM-1 is also preferentially expressed by MZ-T2 B cells, and ~30% of TIM-1$^+$ MZ-T2 B cells express IL-10 [80].

The activation and expansion of Breg cells are critically associated with signaling from Toll-like receptors (TLRs), and CD40 and CD86, but it is not yet clear if BCR-signaling is required [79]. Mice lacking MyD88, TLR2, or TLR4 exclusively on B cells developed a chronic form of EAE, whereas TLR engagement on DCs or monocytes initiated proinflammatory responses. TLR engagement on B cells activated a counter-regulatory effect that damped an excessive inflammatory response. Mice with CD40 deficiency that was restricted to B cells suffered from a more severe EAE and showed a profound decrease of IL-10 production and an increase of encephalitogenic Th1 and Th17 responses. Expression of CD86 on B cells was necessary for mediating recovery of EAE [79]. Breg cells can directly suppress Th1, Th2, and Th17 and also proinflammatory macrophages via their secretion of IL-10 [78]. In addition, Breg cells can augment the induction of Tr1 CD4$^+$ suppressor T cells via their secretion of IL-10, and augment expansion of FoxP3$^+$

CD4$^+$ T cells [79]. Although Breg cells express high levels of CD1d, and CD1d^{hi} B cells were reported to produce IgM autoantibody in lupus mice [81], the influence of Breg cells on CD1d reactive NKT cells is not yet clear.

Tolerogenic dendritic cells

DCs have long been considered as the professional APCs that play crucial roles in linking innate and adaptive immunity; DCs constitute a heterogeneous population of BM-derived cells that can induce both immunity and tolerance [82]. DC tolerogenicity is not specific to a DC subset or restricted to the immature state of the APC. Tolerogenic DCs present antigen to antigen-specific T cells but deliver inadequate costimulatory signals or deliver inhibitory signals for effector T-cell activation and proliferation. This results in conventional T-cell apoptosis and anergy or generation and/or expansion of Treg cells in peripheral lymphoid tissues [83]. The major features of tolerogenic DCs include (1) the ability to acquire and present antigen to antigen-specific T cells; (2) low constitutive expression of surface MHC molecules and low net expression of costimulatory molecules (e.g., CD40, CD80, CD86, OX40L, ICOSL), but high expression of PD-L1; (3) low production of IL-12 and high production of IL-10 and IDO; and (4) resistance to maturation in response to "danger signals," such as high-mobility group box1 protein (HMGB1), TLR ligands, or CD40 ligation [83].

Tolerogenic DCs can be myeloid and plasmacytoid DCs, and the latter are generally more tolerogenic than the former [84]. Tolerogenic DCs can be natural DC subsets such as DCs in the thymus and steady-state CD103$^+$ DCs in intestinal and lung tissues, and also induced DC subsets that develop under abnormal circumstances such as in tumor environments [83]. It is important to stress that there is bidirectional feedback between tolerogenic DCs and Treg cells in mice and humans. For example, under the influence of thymic stromal lymphoietin (TSLP) produced by Hassall's corpuscles, thymic DCs, especially plasmacytoid DCs, augment the development of nTreg cells in the thymus [85]. In peripheral lymphoid tissues, tolerogenic DCs also promote the generation of Treg cells from naïve T cells, and Treg cells make DC progenitors into tolerogenic DCs [86]. An increase in DCs can lead to an increase in Treg cells, whereas the constitutive absence of DCs leads to fatal autoimmunity [79]. Tolerogenic DCs can secrete IL-10, TGF-β, and/or RA to induce naïve T cells into Treg cells; in turn, CTLA-4 on Treg cells can interact with B7 on DCs, resulting in IDO activation and tolerogenic characteristics in DCs [87].

Plasmacytoid DCs can transport peripheral antigens to the thymus to promote central tolerance [88]. Infusion of CCR9$^+$ tolerogenic plasmacytoid DCs suppressed acute GVHD [89], and infusion of dexamethasone-activated tolerogenic DCs prolonged allogeneic skin graft survival [90]. An increase in PD-L1$^+$ plasmacytoid DCs was associated with an increase in Treg cells and liver transplantation tolerance in patients [91].

Myeloid-derived suppressor cells (MDSCs)

MDSCs are defined as cells of myeloid origin with suppressor functions [92]. Although initially described in cancer patients, MDSCs are also present in other inflammatory settings such as solid organ transplantation and allogeneic HCT, in which MDSCs promote organ transplantation immune tolerance, and suppress GVHD [93,94]. Despite their heterogeneity, most MDSCs express common phenotypic markers; mouse MDSCs express CD11b and Gr-1 without MHC II, and human MDSCs express CD11b, CD33, CD34, and low levels of HLA-DR [95]. Myeloid progenitor cells with these markers are not usually suppressive in normal mice and humans, and may subsequently differentiate into macrophages, DCs, and granulocytes [95].

MDSC activation and differentiation are regulated by factors produced by other cells present in the same microenvironment, including stromal cells, activated T cells, and tumor cells [95]. Anti-inflammatory cytokines such as IL-10, TGF-β, IL-13, and IL-4 in the tumor environment can augment MDSC expansion and suppressive function via activation of Stat6 and Stat4 pathways [95]. In transplantation, the ischemic donor allograft and the surgical procedure cause tissue release of inflammatory signals that mobilize BM CD11b$^+$Gr-1$^+$ cells into circulation and infiltration of the graft [96]. The mechanisms of immune suppression by MDSCs include the following: (1) MDSCs can directly suppress proliferation and cytokine production by effector T cells, B cells, and NK cells via producing inducible nitric synthase (iNOs) and arginase 1, and this process requires IFN-γ activation of STAT1 pathway in the MDSC; (2) MDSCs can augment induction of Foxp3$^+$CD4$^+$ Treg cells and indirectly tolerize T cells; this process also requires IFN-γ activation of MDSCs and their production of IL-10 and TGF-β and upregulation of PD-L1 [96].

Other suppressor cells

Tr1 cells

Human CD4$^+$ T cells can be converted into so-called "Tr1" cells in a mixed leukocyte culture in the presence of IL-10. The Tr1 cells are Foxp3$^-$ and suppress effector T-cell proliferation via their secretion of IL-10 and TGF-β; Tr1 cells can function to inhibit GVHD and allograft rejection [97].

DNregulatory T cells

A subset of CD4$^-$CD8$^-$ (double negative, DN) Treg cells have the unique surface phenotype of $\alpha\beta$TCR$^+$CD4$^-$CD8$^-$CD25$^+$CD28$^-$NK1.1$^-$CD30$^+$CD44$^-$ and are distinguished from CD4$^-$CD8$^-$ NKT cells [98]. The DN Treg cells use a unique mechanism of suppression in which trogocytosis and the presentation of allogeneic MHC-peptide complexes are used to target and kill CD8$^+$ T cells with the same TCR specificity, and the killing is Fas–FasL dependent [98]. The DN regulatory T cells were reported to prevent graft rejection, GVHD, and autoimmune diabetes development and also to facilitate the induction of mixed chimerism in non-myeloablatively conditioned recipients [99].

Multipotent mesenchymal stromal cells (MSCs)

MSCs constitute a heterogeneous population of precursor cells, which are found in situ within all mammalian supportive stromal tissue compartments, but BM, adipose tissue, and the umbilical cord are the most commonly used cell sources [100]. The general phenotype is CD73$^+$CD90$^+$CA105$^+$ together with CD11b$^-$CD14$^-$CD34$^-$CD45$^-$CD19$^-$CD79a$^-$HLA-DR$^-$ [100]. MSCs can release a vast array of molecules (e.g., IL-10, TGF-β, galectin 1, galectin 3, and leukemia inhibitory factor) and also bioactive metabolites (e.g., nitric oxide, carbon monoxide, and prostaglandin E2) that have immunomodulating properties [100]. With these secreted factors and cell contact-dependent mechanisms, MSCs suppress CD4$^+$ and CD8$^+$ T-cell proliferation, cytokine production, and cytotoxicity and also modulate DCs and augment generation of Treg cells [100]. Infusion of MSCs has been shown to augment organ transplantation tolerance and prevention of GVHD [101].

Interactions among different suppressor cells

After organ transplantation or HCT, pro- and anti-inflammatory innate and adaptive immune responses are simultaneously activated; innate immune responses are followed by adaptive immune response. Despite the occurrence of active regulation mediated by various suppressor cells in the allograft and in the peripheral lymphoid tissues, rejection and GVHD mediated by inflammatory innate immune cells and alloreactive T cells will dominate in the absence of any other forms of immunosuppressive therapy, as proposed by Wood et al. [39]. Infusion of particular subsets of suppressor cells has been shown to augment suppression of graft rejection or prevention of GVHD, and the infused suppressor cells may interact with other suppressor cells in the recipient. Conditioning with TLI and antithymocyte globulin (ATG) or conditioning with anti-CD3 mAbs was reported to increase the percentage of both NKT and Foxp3$^+$ Treg cells and to prevent allograft rejection and GVHD [32,102]. Recent studies showed that both NKT and Treg cells are required for prevention of GVHD, and NKT cells mediate the Treg cell expansion via their secretion of IL-4 [32]. Hence the optimal effect of suppressor cells may be dependent on the interactions of a network of different types of suppressor cells.

Induction of host immune tolerance to organ allografts

Induction of immune tolerance to allogeneic organ transplants in humans remains the "holy grail" of the field, because tolerance avoids chronic immunosuppressive therapy and prevents acute and chronic rejection. Approaches for induction of immune tolerance in laboratory animal models can be divided into two major categories: non-chimeric approaches that mainly induce peripheral tolerance and chimeric approaches that induce both central and peripheral tolerance.

Major non-chimeric transplantation tolerance-inducing regimens

Many reagents, such as chemical immunosuppressants, anti-CD3, anti-CD4, anti-CD8, anti-CD52 mAbs, and ATG, have been used to prevent graft rejection, but only some of the regimens have been shown to be able to induce immune tolerance in at least mouse models. Below is a summary of the major regimens.

Costimulatory blockade for induction of transplantation tolerance

Costimulatory signals are critical for optimal T-cell activation, proliferation, and differentiation, and blockade of costimulatory signals is proposed to induce T-cell anergy and apoptosis; blockade of interactions between CD28–CD80/CD86, CD40L–CD40, or LFA-1/ICAM-1 has been reported to augment induction of transplantation tolerance in mouse models, but not yet in non-human primates or humans [103]. The challenges for translating tolerance inducing costimulatory blockade regimens from mouse to non-human primates or humans may explained by the following barriers. (1) Non-human primates and humans may have a higher frequency of alloreactive T-cell precursors, because in a mouse model naïve T cells present at high frequency appear not to require costimulation during priming, and fewer proliferation cycles are needed to generate sufficient activated T cells to mediate graft rejection [104]. (2) Non-human primates and humans may have a higher frequency of alloreactive memory T cells, which can derive from prior transplantation, blood transfusion, pregnancy or environmental exposure to pathogens. Pathogen-specific memory T cells may exhibit cross-reactivity with allogeneic peptide: MHC ligands [105], and the memory T cells can possess a lower activation threshold [106]. (3) Infection and tissue damage in the process of organ transplantation may prevent the induction of immune tolerance or break down immune tolerance induced by costimulatory blockade and donor-specific infusion [107]. Thus, a regimen that combines T-cell-reducing reagents with costimulatory blocking reagents that target not only naïve but also memory T cells may be required for induction of transplantation immune tolerance in humans.

Blockade of the CD28/CD80/CD86 pathway by CTLA4-Ig induced immune tolerance of islet or heart transplants in mouse models [108,109], but administration of CTLA-4-Ig only moderately prolonged renal graft survival in non-human primates [110]. LEA29Y, a second-generation CTLA-4-Ig with increased avidity, showed a 10-fold increase in inhibiting T-cell activation in vitro and also significantly prolonged graft survival in non-human primates compared with the original CTLA-4-Ig. LEA29Y also markedly improved graft survival when used as part of a combined immunosuppressive regimen containing either MMF and steroids or anti-IL-2R [111]. Phase II and III clinical trials showed that combination immunotherapy with LEA29Y (belatacept) is effective in reducing immunosuppressants in renal transplantation patients [112].

Administration of humanized anti-CD80/CD80 mAbs significantly prolonged renal graft survival in non-human primates [113], and was also safe in a phase I clinical trial [114], but phase II trials to evaluate efficacy have not been reported. Both antagonistic and agonistic anti-CD28 mAbs augmented the induction of transplantation tolerance in mouse models, although with different mechanisms: the former inhibited T-cell proliferation and the later augmented T-cell apoptosis [115,116]. Unfortunately, agonistic anti-CD28 caused T-cell hyperactivation and a severe cytokine storm in humans [117]. However, an antagonistic anti-CD28 mAb that specifically blocks CD28–CD80/CD86 interaction augmented CTLA-4-mediated immune regulation, expanded Treg cells and significantly prolonged cardiac graft survival when used in combination with the calcineurin inhibitor cyclosporine [118].

Blockade of CD40L–CD40 interactions via anti-CD40L mAb leads to inhibition of DC maturation and T-cell activation [119], augmentation of T-cell secretion of immunomodulatory cytokines and T-cell apoptosis [120], depletion of activated T cells [121], and augmentation of the generation of FoxP3$^+$ Treg cells from conventional CD4$^+$ T cells [122]. Administration of anti-CD40L in combination with CTLA-4-Ig induced tolerance of skin and cardiac grafts in mouse models [123] and prevented rejection of renal grafts in non-human primates [124]. Administration of humanized anti-CD154 alone with an extended course was also able to prevent acute renal allograft rejection in non-human primates [125]. Additionally, administration of CTLA-4-Ig and anti-CD154 in combination with rapamycin but not cyclosporine was able to induce immune tolerance for not only cardiac but also skin grafts in mouse models [126]. Treatment with donor-specific cell transfusions (DSTs) in combination with anti-CD40L markedly prolonged the survival of allo-skin grafts and deleted alloreactive T cells in a CTLA-4-dependent manner [127]. Combination therapy with DST, anti-CD40L, and rapamycin prolonged allo-skin graft survival in non-human primates, which was considered to be one of the most promising costimulatory blockade regimens for augmenting graft survival [128]. Unfortunately, a clinical trial using anti-CD154 mAb was halted following evidence of unanticipated thromboembolic side effects

[129]. Alternatively, humanized anti-CD40 mAbs were developed, and administration of anti-CD40 with CTLA-4-Ig (LEA29Y) significantly prolonged islet allograft survival in non-human primates [130], but no human trial has yet been reported.

The LFA-1/ICAM interaction plays an important role in formation of the immunological synapse, T-cell activation, and migration [131]. LFA-1 blockade attenuated T-cell activation, inhibited T-cell migration into inflammatory sites, and confined effector and regulatory T cells in lymph nodes [132]. Blockade of LFA-1/ICAM interaction via anti-LFA-1 and anti-ICAM-1 was initially reported to induce immune tolerance for cardiac and skin allografts in mice [133]. Anti-LFA-1 treatment had a synergistic effect with anti-CD40L in inducing immune tolerance for hepatocyte allografts [134]. Humanized anti-LFA-1 mAb was able to prolong significantly the survival of cardiac grafts in rhesus monkeys when used with immunosuppressants [135]. More recent reports showed that anti-LFA-1 mAb could target memory T cells and a combination therapy of anti-LFA-1 and CTLA-4-Ig or a combination therapy of anti-LFA-1, anti-IL-2Rα, and sirolimus resulted in long-term survival of islet allografts in rhesus monkeys, although single use of those reagents did not have an effect [136]. The CD2-specific fusion protein alefacept (LFA-3-Ig) that specially eliminates memory T cells in combination with CTLA-4-Ig prevented renal allograft rejection and alloantibody formation in non-human primates [137]. Hence a costimulatory blockade regimen that can both eliminate memory T cells and induce naïve T-cell tolerance may represent a novel approach for induction of organ transplantation tolerance.

Anti-CD4 mAb treatment for induction of transplantation tolerance

Administration of non-depleting anti-CD4 and anti-CD8 mAbs in combination with donor BM and T-cell-depleted spleen cells was initially shown to induce immune tolerance for skin grafts from MHC-matched donors in mouse models [138]. Subsequently, the $CD4^+$ T cells from the primary tolerant recipients were found to be able to tolerize naïve T cells in the adoptive recipients, and this phenomenon was called "infectious tolerance" [139]. The suppressor $CD4^+$ T cells were finally found to be $CD25^{hi}FoxP3^+CD4^+$ Treg cells [47]. On the other hand, administration of depleting anti-CD4 mAb that markedly reduced but not completely eliminated $CD4^+$ T cells in combination with DST was reported to induce immune tolerance for cardiac allografts in fully MHC-mismatched recipients, and the tolerance was associated with the presence of suppressive $CD4^+$ T cells in the recipients [140]. The suppressor $CD4^+$ T cells in the tolerant recipients were also subsequently found to be thymus-derived nTreg cells [141]. Anti-CD4 mAb could selectively expand alloantigen-specific $Foxp3^+$ Treg cells [142]. Clinical translation of either depleting or non-depleting anti-CD4 regimens has not been reported.

Other regimens that can potentially augment induction of transplantation tolerance

Treatment with a non-FcR-binding and non-depleting anti-CD3 mAb was reported to induce immune tolerance for cardiac but not skin allografts in a rat model, and the tolerance induction was associated with induction of Th2 cells and T-cell anergy [143]. A study showed that non-depleting anti-CD3 mAbs selectively depleted activated pathogenic T cells while augmenting nTreg cells with expression of Helio and preserving nTreg cells [144]. Administration of non-depleting anti-CD3 at an appropriate time (~7 days) after transplantation was able to induce immune tolerance for islet allografts [145]. Simultaneous T-cell depletion with ATG and costimulatory blockade with CTLA-4-Ig in combination with rapamycin markedly prolonged skin allograft survival in mouse models, in which effector T cells were reduced and Treg cells were expanded [146]. Treatment of renal transplantation patients with alemtuzumab (anti-CD52, Campath-1H) that depletes T, B, NK, and monocytes in combination with low-dose calcineurin inhibitors could achieve graft acceptance with reduced immunosuppression, which was associated with increased Breg and $Foxp3^+CD4^+$ Treg cells [1,46,147,148].

Although conventional T cells can be induced to express Foxp3 transiently and then become pathogenic T cells in the inflammatory environment, "true" Treg cells that have DNA demethylation of the Foxp3 locus do not become pathogenic T cells [149]. Ex vivo expanded alloantigen-specific nTreg cells are powerful in suppressing rejection of heart allografts in rat models [150], and a multicenter phase I/II clinical trial of cell therapy including expanded nTreg cells, Tr1 cells, myeloid suppressor cells, and tolerogenic DCs in living-donor kidney transplantation is ongoing [151].

Clinical regimens for induction of chimerism and transplantation tolerance

Chimerism is established after donor hematopoietic stem cells (HSCs) and other progenitors engraft in an allogeneic recipient and develop into lympho-hematopoietic cells that persist in the recipient. When a donor stem-cell-derived lympho-hematopoietic system totally replaces that of the host, it is called complete chimerism; and when donor- and host-type lympho-hematopoietic systems coexist in a recipient, it is called mixed chimerism. The major obstacle for donor stem-cell engraftment is the rejection mediated by host T, B, NK, and other cells, and alloreactive host T cells play a dominant role. Mixed and complete chimerism can be induced via allogeneic HCT after myeloablative or non-myeloablative conditioning of the recipient.

Classical allogeneic HCT was designed for the treatment of patients with hematologic malignancies, in which recipients were usually conditioned with myeloablative or non-myeloablative TBI or high-dose chemotherapy. The patients usually developed complete chimerism, and the pre-existing donor-reactive host-type T cells were eliminated by the conditioning TBI and/or the infused donor T cells in the transplants. The de novo development of donor-reactive T cells after HCT is negatively selected by donor-type APCs in the thymus in the absence of GVHD. The infused donor T cells in transplants can mediate GVHD and graft-versus-leukemia effects (GVLEs). HCT regimens have been used not only for the treatment of malignancies in humans, but also for the induction of organ transplantation immune tolerance. Clinical protocols using this approach are summarized below.

Stanford clinical tolerance induction regimen (mixed chimerism)

TLI was originally used as a curative therapy for Hodgkin lymphoma by Kaplan and colleagues at Stanford University Medical Center. In the late 1970s, the non-myeloablative TLI procedure was adapted to laboratory animal studies by Stanford investigators as a conditioning regimen for BM transplantation to achieve mixed chimerism in MHC-mismatched mice and rats. The animals developed mixed chimerism, showed no signs of GVHD, and were tolerant to donor-type skin and heart allografts [152]. This was the first demonstration that stable mixed chimerism could be established in adult laboratory animals.

In order to accommodate the clinical situation of deceased donor organ transplantation, in which timing of the availability of the graft is not predictable, the conditioning regimen was changed to perform the TLI and administration of ATG after organ transplantation was in place [153–156]. Accordingly, the rats or mice were given TLI and ATG right after organ transplantation and an injection of donor BM cells immediately after conditioning[153–156]. The resultant mixed chimeras were tolerant to donor skin and cardiac grafts and showed no signs of GVHD[153–156]. The recipients conditioned with TLI and ATG were highly resistant to GVHD induction when donor spleen cells were added to donor BM cells to induce complete chimerism, as compared with recipients conditioned with TBI [157]. The prevention of GVHD was associated with the enrichment of residual host-type NKT cells that suppress GVHD via their secretion of IL-4 that activated donor-type Treg cells [157]. In addition to central thymic deletion due to the engraftment of donor APCs in the thymus, NKT and Treg cells in the periphery also contribute to donor graft immune tolerance, because NKT-deficient CD1d$^{-/-}$ or Ja18$^{-/-}$ recipients with mixed chimerism still reject donor cardiac grafts [158], and deletion of Treg cells with anti-CD25 mAb also caused donor-graft rejection [159]. Tolerance is dependent on the interaction between the host NKT cells and host Treg cells such that the Treg cells are polarized to IL-10 secretion after exposure to NKT cell derived IL-4 [160]. Similarly, myeloid derived suppressor cells (MDSCs) are required for tolerance induction after interaction with NKT cells in an IL-4 dependent manner [161]. Thus, a network of regulatory cells contributes to prevention of both GVHD and graft rejection in this protocol (Figure 12.1).

The TLI and ATG conditioning regimen was first used in the context of HLA-matched HCT to treat leukemia and lymphoma patients to induce complete chimerism. Consistent with observations with mouse models, the conditioning regimen significantly reduced GVHD but retained anti-tumor (GVT) effects in these patients [162]. The regimen was modified for induction of mixed chimerism in HLA-matched renal transplantation patients. The recipients were given TLI post-transplantation and ATG, starting with an intra-operational infusion. Thereafter, the recipients were infused with granulocyte colony-stimulating factor (G-CSF) mobilized donor CD34^{+} progenitor cells and CD3^{+} T cells. It was found that 17/22 patients developed multilineage mixed chimerism without signs of GVHD; 18 chimeric recipients were withdrawn from immunosuppressive drugs without subsequent rejection episodes. The tolerance was associated with early high ratios of CD4^{+}CD25^{+} Treg and NKT cells versus conventional naïve CD4^{+} T cells; and the T cells from the tolerant recipients showed specific upresponsiveness to donor alloantigens [163,164]. These studies demonstrate that TLI and ATG conditioning can promote the development of persistent mixed chimerism and transplantation immune tolerance in HLA-matched humans. Ongoing studies are applying the approach to haplo-matched or total HLA-mismatched recipients.

MGH clinical tolerance induction regimen (mixed chimerism)

In the early 1980s, Investigators at Massachusetts General Hospital (MGH) used a mixture of T-cell-depleted (TCD) BM cells from both donor and host to induce mixed chimerism in myeloablative TBI-conditioned allogeneic or xenogeneic rodent recipients, and the mixed-chimeric recipients showed specific immune tolerance to the donor-type skin grafts [165]. To avoid the toxicity of myeloablative TBI, the investigators developed a non-myeloablative conditioning regimen consisting of 3 cGy TBI, 700 cGy thymic irradiation, and depleting anti-CD4 and anti-CD8 mAbs; with this conditioning regimen, infusion of donor whole BM cells was able to induce

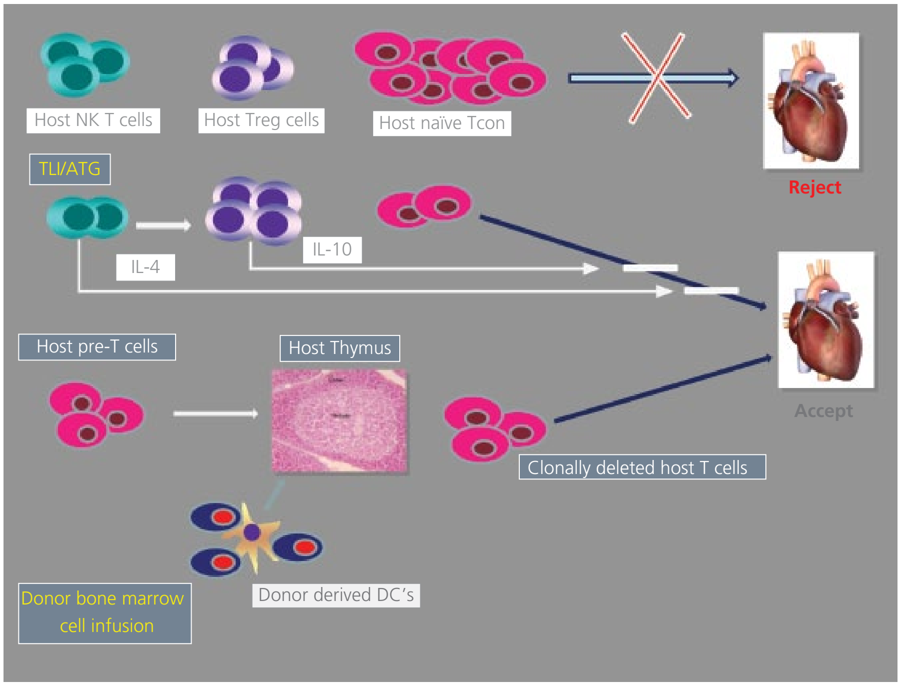

Figure 12.1 Cellular interactions that promote tolerance to combined hematopoietic cell and organ transplants after conditioning with total lymphoid irradiation and antithymocyte globulin. The conditioning regimen alters the balance of T-cell subsets to reduce the number of naïve T cells compared with NKT cells and Treg cells due to differences in the radiosensitivity of the subsets. After conditioning, the host NKT cells secrete IL-4 that activates host Treg cells to secrete IL-10. The NKT cells and the Treg cells and their secretion of these cytokines are required to suppress the ability of the host naïve T cells to reject the donor hematopoietic cells and organ graft. Once the donor hematopoietic cells engraft and establish mixed chimerism, the host T cells and precursors are negatively selected, resulting in clonal deletion against donor alloantigens. Tolerance is promoted by a combination of immune regulation and clonal deletion.

mixed chimerism in fully MHC-mismatched allogeneic mouse recipients, and the recipients developed tolerance to donor skin graft [166]. Intra-thymic deletion was the major mechanism maintaining donor-specific tolerance in this model [167,168]. The investigators developed an even less toxic conditioning regimen in mice, using costimulatory blockade of anti-CD40L and CTLA-4-Ig to replace thymic irradiation and depleting antibodies [16]. In this regimen, costimulatory blockade and infusion of donor BM cells mediated early tolerization of the pre-existing donor-reactive $CD4^+$ and $CD8^+$ T cells to allow the establishment of mixed chimerism [169,170]. The long-term tolerance was also maintained by the intrathymic deletion in the mixed chimeras. Other studies found that host-type Treg cells also contributed to induction and maintenance of tolerance in the recipients with mixed chimerism established by costimulatory blockade regimens [171].

The modified laboratory animal conditioning regimen was applied to humans for induction of mixed chimerism and renal transplantation immune tolerance. First, patients with multiple myeloma and end-stage renal disease were conditioned with cyclophosphamide, equine ATG, and thymic irradiation, and then transplanted with BM and kidney from HLA-matched donors. Sixty days after transplantation, the patients were given donor lymphocyte infusion. Seven patients developed chimerism, and three patients had long-term normal or near- normal renal function after withdrawal of immunosuppressants; the mixed chimeras showed no signs of GVHD but the complete chimeras showed signs of chronic GVHD that required immunosuppressive drug therapy [172]. The conditioning regimen was further modified for induction of renal transplantation tolerance in non-tumor HLA haplotype-matched patients with end-stage renal disease. Patients were conditioned with cyclophosphamide, anti-CD2 mAb and thymic irradiation, and then transplanted with donor BM and renal grafts. Despite only transient mixed chimerism in the first 5 patients, kidney graft acceptance without immunosuppression was observed in four patients and one patient had early graft loss due to humoral rejection. The graft acceptance was associated with donor-specific unresponsiveness in proliferative and cytotoxic assays in addition to an increased proportion of $Foxp3^+CD4^+$ Treg cells [173,174]. However, a follow-up study with a total of 10 patients showed 2/10 with early graft loss and another with chronic rejection, and 9/10 patients with engraftment syndromes with marked transient graft dysfunction. Although immunosuppressive drugs were discontinues in seven patients, graft injury limits this approach [175].

Northwestern clinical tolerance induction regimen (complete chimerism)

Complete chimerism induced in NOD mice with myeloablative conditioning and transplantation of MHC-mismatched donor T cell-depleted BM or BM stem cells provided immune tolerance to donor islet grafts without causing GVHD [176]. Complete chimerism using a non-myeloablative conditioning regimen has been reported to induce renal transplant acceptance without causing GVHD in five HLA-mismatched patients who were conditioned with two doses of cyclophosphamide, 200 cGy TBI, and three doses of fludarabine, followed by injection of donor BM, facilitating cells, and low-dose donor T cells [177]. Post-transplantation immunosuppression was with tacrolimus and mycophenolate mofetil. The patients with complete chimerism were completely withdrawn from immunosuppressive drugs without subsequent rejection [177]. The stable chimerism was induced in about half of the patients, and the rest lost chimerism [178,179]. However, there is concern about the immune function of full HLA-mismatched complete chimeras, as one of the five recipients suffered a near-lethal infectious complication associated with loss of renal graft [177].

In addition, a complete replacement of the host-type lymphohematopoietic system with the donor-type cells is associated with a considerable risk of acute or chronic GVHD. The acceptance of donor organ transplants by complete donor chimeras is not an example of host-versus-donor immune tolerance, since host immune cells are not present. Mixed chimeras can still generate donor-reactive host-type T cells in the thymus, and mixed chimerism can mediate both central and peripheral tolerance of donor-reactive T cells. The donor-derived APCs mediate thymic negative selection of the newly developed donor-reactive host-type T cells after transplantation, and Treg and NKT cells can control the residual donor-reactive T cells in the periphery [17,158]. In the mixed chimeras established with myeloablative TBI conditioning and infusion of both donor- and host-type TCD BM cells, thymic deletion is sufficient for prevention of rejection of donor organ transplants [168]. In the mixed chimeras established with non-myeloablative conditioning regimen such as TLI or costimulatory blockade, in addition to central deletion, host- and donor-type regulatory T cells such as NKT and Treg cells in the periphery are also required to prevent residual host peripheral T cells from rejecting the donor organ transplants [158,180]. This deletional and regulatory tolerance provided by mixed chimerism is particularly robust and allows acceptance of highly immunogenic primary skin or small bowel grafts across the most extensive histocompatibility barriers [17].

Radiation-free regimen for induction of mixed chimerism

Low-dose TBI, TLI, or thymic irradiation was used in the Stanford, MGH, and Northwestern conditioning regimens for induction of chimerism and tolerance as discussed above. Investigators are also searching for a radiation-free conditioning regimen to reduce side effects for induction of mixed chimerism. Below is a summary of major radiation-free conditioning regimens:

1. *Costimulatory blockade-based regimens:* Wekerle et al. reported that injection of mega-doses of donor BM cells and administration of anti-CD40L and CTLA-4-Ig were able to induce stable mixed chimerism and donor-specific immune tolerance in MHC-mismatched non-autoimmune mouse recipients without cytoreductive conditioning. Infusion of host-type $FoxP3^+CD4^+$ Treg cells was able to augment donor cell engraftment and reduce the required donor BM cell dose [181,182]. This regimen has not been attempted in autoimmune mice or large animal models.
2. *Anti-CD3/CD8 mAb-based conditioning regimens:* Pre-existing alloreactive memory T cells in autoimmune mice and also in laboratory large animals and humans are resistant to tolerance induction by costimulatory blockade and remain a major obstacle for induction of mixed chimerism. Donor $CD8^+$ T cells play a major role in facilitating donor stem-cell engraftment and are less powerful in inducing GVHD than $CD4^+$ T cells [74,183,184]. In addition, $CD4^+$ T cells can interfere with donor stem-cell engraftment [184]. Tissue damage caused by TBI- or high-dose chemotherapy-conditioning plays a major role in initiating GVHD [185,186]. Therefore, investigators at the City of Hope National Medical Center designed a radiation-free anti-CD3/CD8 mAb conditioning regimen followed by the infusion of donor BM and $CD4^+$ T-depleted spleen cells for induction of chimerism in autoimmune mice.

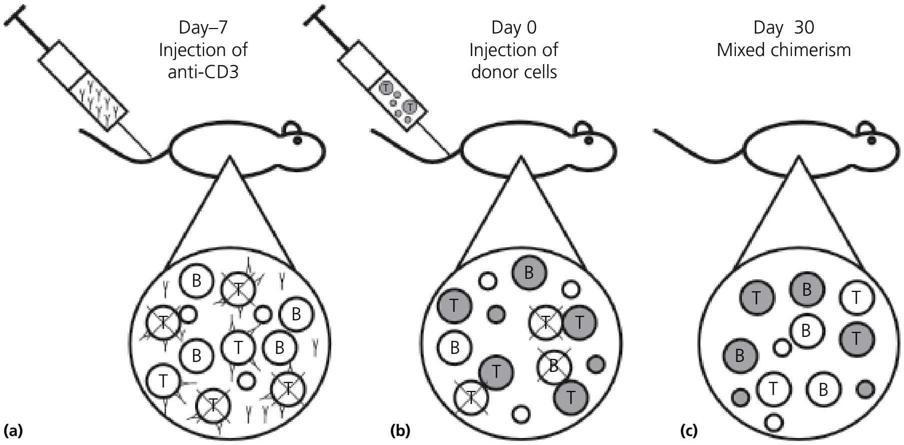

Figure 12.2 Anti-CD3/CD8 conditioning for induction of mixed chimerism. Recipient mice are injected with anti-CD3 and anti-CD8 mAbs to deplete a majority of recipient T cells, and the remainder of surviving T cells downregulate their expression of the T-cell receptor (a). Seven days after conditioning, the injected antibodies have been cleared from the system and donor T cells and stem cells (shaded cells) are injected into recipient mice. The donor T cells are activated and kill the disarmed residual host T cells that express little TCRs to prevent rejection of donor stem cells and facilitate engraftment without inducing (b). By 30 days post-HCT, the newly developed donor- and host-type T cells from progenitors begin to repopulate the system and establish mixed chimerism (c).

As depicted in Figure 12.2, recipient mice were conditioned with anti-CD3/CD8 mAbs to deplete host T cells partially and downregulate the TCR–CD3 complex on residual host T cells. The host T cells did not re-express their TCRs until ~10 days after antibody injection. Infusion of donor BM and CD4$^+$ T-depleted spleen cells (CD8$^+$ T cells) at 7 days after antibody injection avoided the negative impact of anti-CD3/CD8 mAb on donor CD8$^+$ T cells, because antibodies were undetectable at that time. The latter cells can kill the disarmed host T cells to facilitate donor cell engraftment. Under this radiation-free ant-CD3/CD8-conditioning regimen, both non-autoimmune and autoimmune mice developed mixed and complete chimerism depending on the dose of infused donor CD4$^+$ T-depleted spleen cells, and neither mixed nor complete chimeras showed any signs of GVHD [102,187]. The mixed chimerism with MHC-mismatched donor BM was able not only to tolerize alloimmunity and provide long-term donor-specific tolerance in non-autoimmune recipients but also to tolerize autoreactive T cells and reversed autoimmunity in mice with type 1 diabetes and also in mice with systemic lupus [188,189].The GVHD prevention by the radiation-free anti-CD3/CD8 conditioning regimen is explained by multiple mechanisms, including (1) avoidance of tissue damage caused by TBI or high-dose chemotherapy; (2) depletion of CCR7$^+$ DCs in draining lymph nodes that imprint donor T-cell tissue homing and chemokine receptors and also reduction of GVHD target tissue release of chemokines, such that donor T cells were prevented from migration into GVHD target tissues [190,191]; (3) maintenance of a high percentage of NKT and Treg cells among residual host T cells that can prevent GVHD [102]; (4) maintenance of tissue expression of protective molecules such as B7-H1 (PD-L1), so that infiltrating T cells can be tolerized [192]; and (5) conversion of injected CD8$^+$ T cells into regulatory T cells such as FoxP3$^+$CD8$^+$ T cells in the long-term chimeras [187].

The major obstacle for translating this radiation-free anti-CD3/CD8 mAb conditioning regimen into clinical application is the cytokine storm triggered by FcR-binding intact anti-CD3 [193]. Although conditioning with FcR-non-binding anti-CD3 mAbs that do not cause a cytokine storm failed to facilitate induction of mixed chimerism, sequential injection of FcR-non-binding and FcR-binding anti-CD3 was able to avoid a cytokine storm and facilitate the induction of mixed chimerism in late-stage diabetic non-obese diabetic (NOD) mice and re-establish central and peripheral tolerance [194–197].

Summary and future directions

Seventy years after Medawar and colleagues' first report about induction of transplantation tolerance in mice, induction of chimerism and transplantation immune tolerance in adult humans has finally been realized in small numbers of renal transplantation patients who received donor hematopoietic cell grafts [163,164,173,174,177,178]. In order to promote the wider application of induction of chimerism and transplantation tolerance, much more work needs to be done, including expansion to all live or deceased donor transplants of a variety of organs. Simpler and less toxic procedures such as radiation-free clinical tolerance regimens and also those that do not require chimerism are likely to be tested in the future.

Acknowledgments

We thank Jeremy Racine, Miao Wang, James Young and Kaniel Cassady in Defu Zeng's laboratory for their assistance with literature searches. We apologize to colleagues whose work is not cited in this chapter due to space limitations.

CHAPTER 13

The Pathophysiology of Graft-versus-Host Disease

James L.M. Ferrara[1] **and Joseph H. Antin**[2]

[1] Hematologic Malignancies Translational Research Center, Tisch Cancer Institute, Icahn School of Medicine at Mount Sinai, New York, NY, USA

Acute GVHD pathophysiology: a three-step model

Acute graft-versus-host disease (GVHD) results from complex interactions between donor T cells and host tissues in an inflammatory milieu. The pathophysiology of acute GVHD can be considered as a three-step process involving both the innate and adaptive immune systems (Figure 13.1). The three steps are (1) tissue damage in the recipient by the conditioning regimen, (2) donor T-cell activation and clonal expansion, and (3) cellular and inflammatory factors. Intrinsic to this schema is the role of mononuclear phagocytes and other accessory cells in complex interactions with cytokines secreted by activated donor T cells.

In *step 1*, the conditioning regimen leads to damage and activation of host tissues throughout the body. The inflammatory cytokines and chemokines enhance donor T-cell recognition of host alloantigens by increasing the expression of major histocompatibility complex (MHC) antigens, adhesion receptors, and other molecules on host antigen-presenting cells (APCs). An important aspect of the gastrointestinal (GI) mucosal injury is the resultant leakage of endotoxins and pathogen-associated molecular products (PAMPs) into the circulation, resulting in activation of innate immune cells through Toll-like receptors (TLRs).

In *step 2*, host and most likely donor APCs present alloantigen in the form of a peptide–human leukocyte antigen (HLA) complex to the resting T cells. Costimulatory signals are required for T-cell activation, and these signals further activate APCs and enhance T-cell stimulation. T-cell activation is characterized by cellular proliferation and the secretion of cytokines. Regulatory T (Treg) cells that can act as a powerful brake on the graft-versus-host (GVH) reaction also expand at this time.

In *step 3*, effector functions of mononuclear phagocytes, natural killer (NK) cells, and neutrophils are triggered through a secondary signal provided by mediators, such as lipopolysaccharide (LPS) that leak through the damaged intestinal mucosa. Release of inflammatory cytokines stimulates host tissues to produce inflammatory chemokines that direct effector cells into target organs. This mechanism amplifies local tissue injury and promotes an inflammatory response which leads to target tissue destruction.

Step 1: effects of conditioning

Prior to hematopoietic cell transplantation (HCT), a patient's tissues have been damaged by underlying disease and its treatment, infection, and transplant conditioning. Conditioning regimens activate host APCs that are critical to the stimulation of donor T cells infused in the stem-cell inoculum. This process helps explain a number of unique and seemingly unrelated aspects of GVHD. For example, the risk of GVHD increases with advanced-stage leukemia, certain intensive conditioning regimens, and histories of viral infections [1]. Total body irradiation (TBI) is particularly important in this process because it activates host tissues to secrete cytokines, such as tumor necrosis factor- α (TNF-α) and interleukin-1 (IL-1) [2], and it induces endothelial and epithelial cell damage in the GI tract [3]. Further damage by GVHD effectors amplifies GI tract and systemic GVHD by allowing the translocation of LPS and PAMPs into the systemic circulation. The relationship between conditioning intensity, inflammatory cytokines, and GVHD severity has been confirmed by animal models [4] and clinical observations [1].

Step 2: Donor T-cell activation and cytokine secretion

Donor T-cell activation

Murine studies have demonstrated that host APCs alone are both necessary and sufficient to stimulate donor T cells [5]. Donor T cells migrate to secondary lymphoid organs, such as Peyer's patches, lymph nodes, and the spleen, where they encounter host APCs [6]. Immediately after HCT, both host- and donor-derived APCs are present in secondary lymphoid organs. Donor T-cell receptors (TCRs) can recognize alloantigens on either host APCs (direct presentation) or donor APCs (indirect presentation). During direct presentation, donor T cells recognize either the minor histocompatibility antigens (mHAs) bound to allogeneic MHC molecules or the foreign MHC molecules themselves. During indirect presentation, T cells respond to allogeneic peptides generated by degradation of host proteins that are then presented by donor MHCs [7]. In GVHD to mHAs, direct presentation is dominant because APCs derived from the host rather than from the donor are critical [8]. Several laboratories have shown that naïve ($CD62L^+$) T cells cause experimental GVHD whereas memory ($CD62L^-$) T cells do not, although memory stem cells may be involved [9].

TCR signaling after antigen recognition induces a conformational change in adhesion molecules, resulting in higher-affinity binding to the APCs [10]. Full T-cell activation also requires costimulatory signals provided by APCs. Currently, there are four known CD28

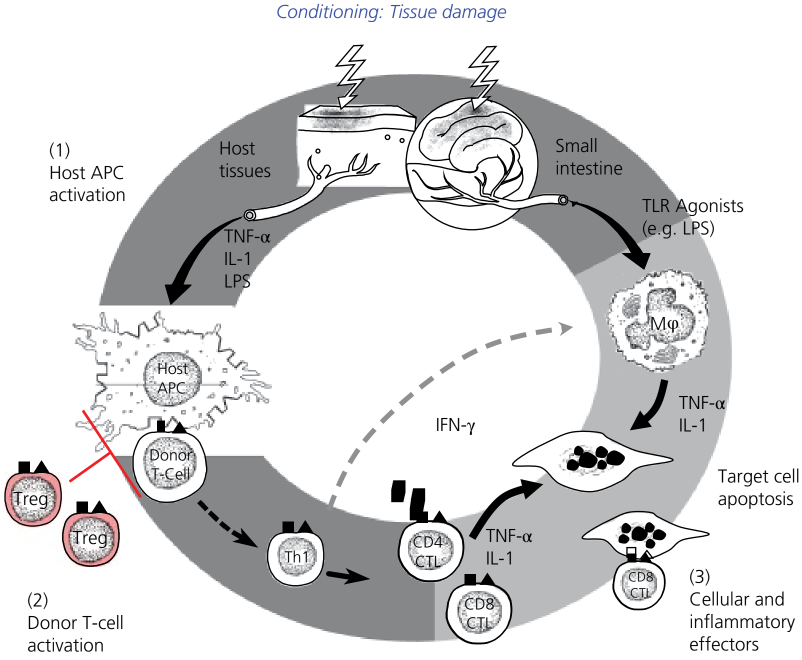

Figure 13.1 The pathophysiology of a acute graft-versus-host disease (GVHD). GVHD pathophysiology can be summarized in a three-step process.

superfamily members expressed on T cells: CD28, cytotoxic T-lymphocyte antigen 4 (CTLA-4), inducible costimulator, and programmed death-1 (PD-1). In addition, there are four TNF receptor family members: CD40 ligand (CD154), 4–1BB (CD137), OX40, and herpes simplex virus glycoprotein D or herpes virus entry mediator. The best-characterized costimulatory molecules, CD80 and CD86, deliver positive signals through CD28 that lower the threshold for T-cell activation and promote T-cell differentiation and survival, whereas signaling through CTLA-4 is inhibitory [11].

The most potent APCs are dendritic cells (DCs); however, the relative contribution to the development of GVHD of DCs and other semiprofessional APCs, such as monocytes/macrophages and B cells, remains to be elucidated. Donor APCs may also amplify GVHD, but in the skin, Langerhans cells of host origin appear to be essential for the activation of donor T cells [11]. Signaling through TLRs and through other innate immune receptors such as non-obese diabetic (NOD) receptors may act as "danger signals" and activate host APCs, amplifying the donor T-cell response [12]. Release of damage-associated molecular patterns (DAMPs) activates the inflammasome, a multicomponent multimer that leads to the activation of the caspase 1 cascade. Agents that mediate epigenetic changes, such as the histone deacetylase inhibitor vorinostat, may also suppress T-cell activation through reducing the DC response [13].

Cytokine secretion by donor T cells

Several factors influence the ability of DCs to instruct naïve CD4$^+$ T cells to secrete cytokines. These factors include the type and duration of DC activation along with the DC:T-cell ratio and the proportions of DC subsets present during T-cell interactions [14]. IL-2 has a pivotal role in both controlling and amplifying the immune response against alloantigens. The addition of low doses of IL-2 during the first week after allogeneic bone marrow transplantation can enhance the severity and mortality of GVHD [15]. Monoclonal antibodies (mAbs) against IL-2 or its receptor can prevent GVHD when administered shortly after the infusion of T cells [16], but this strategy was only moderately successful in reducing the incidence of severe GVHD [17]. IL-15 is another critical cytokine in initiating allogeneic T-cell division in vivo [18], and elevated serum levels of IL-15 are associated with acute GVHD in humans [19].

Increased levels of IFN-γ are associated with acute GVHD [20], and a large proportion of T-cell clones isolated from GVHD patients produce IFN-γ [21]. Cytotoxic T-lymphocytes (CTLs) that are specific for mHAs and produce IFN-γ also correlate with the severity of GVH reaction in a skin-explant assay of human disease [22]. IFN-γ enhances antigen presentation and recruits effector cells into target organs [23]. Concomitantly, IFN-γ alters target cells so that they are more vulnerable to damage during GVHD. IFN-γ also mediates GVHD-associated immunosuppression seen in several experimental HCT systems in part by the induction of nitric oxide (NO) [24]. At early time points after HCT, IFN-γ may paradoxically reduce GVHD by enhancing Fas-mediated apoptosis of activated donor T cells [25]. High doses of exogenous IL-2 early after bone marrow transplantation protect animals from GVHD mortality [26]. It has been suggested that IL-2 mediates its protective effect via inhibition of IFN-γ [20]. Such paradoxes may be explained by the complex dynamics of donor T-cell activation, expansion, and contraction. The complex role of various cytokines in mediating GVHD damage has recently been reviewed [27].

Regulatory T cells

In both humans and mice, Treg deficiency results in immune dysregulation and autoimmunity (see Chapter 14]. The IPEX syndrome in humans results from loss of function mutations of *FOXP3* [28], and scurfy mice lack the transcription factor FOXP3 [29], resulting in an analogous syndrome. *FOXP3* appears to function as a master control gene for the development and function of natural Treg cell, which normally constitute approximately 5–10% of the circulating CD4$^+$ T-cell population. Treg cell suppress both innate and adaptive immune functions [30] by producing inhibitory cytokines (IL-10 and transforming growth factor-beta (TGF-β) and also by cell contact-dependent inhibition of APC function [30]. Addition of purified CD4$^+$CD25$^+$ Treg populations can suppress the proliferation of conventional T cells and prevent GVHD [31]. The ability of extracorporeal photopheresis to reduce experimental GVHD depends on its induction of Treg cell [32]. The use of calcineurin inhibitors and thymic injury from GVHD may interfere with the development of adequate numbers of Treg cells that can control GVHD [33]. Another regulatory population consists of NK1.1$^+$ T cells. Both peripheral blood and marrow NK1.1$^+$ T cells can prevent GVHD by their IL-4 secretion [34].

Step 3: cellular and inflammatory effectors

The pathophysiology of acute GVHD culminates in the generation of multiple cytotoxic effectors that contribute to target tissue injury. Extensive experimental and clinical data suggest that soluble inflammatory mediators act in conjunction with direct cell-mediated cytolysis by CTL and NK cells to cause the full spectrum of damage. As such, the effector phase of GVHD involves aspects of both the innate and adaptive immune response, and the synergistic interactions of components generated during steps 1 and 2.

Cellular effectors

Following recognition of a target cell through TCR–MHC interaction, CTLs insert perforin into the target cell membrane, forming “perforin pores” that allow granzymes to enter the cell and induce apoptosis through various downstream effector pathways [35]. Ligation of Fas results in the formation of the death-inducing signaling complex and the subsequent activation of caspases [36]. A number of ligands on T cells also possess the capability to trimerize TNF-α receptor (TNFR)-like death receptors (DRs) on their targets, such as TNF-related apoptosis-inducing ligand (TRAIL:DR4,5 ligand) and TNF-like weak inducer of apoptosis (TWEAK:DR3 ligand) [37].

Lethal GVHD occurs even in the *absence* of perforin-dependent killing, demonstrating that the perforin/granzyme pathway plays a significant, but not exclusive, role in target organ damage. CD4$^+$ CTLs preferentially use the Fas/FasL pathway during acute GVHD, whereas CD8$^+$ CTLs primarily use the perforin/granzyme pathway, consistent with other conditions involving cell-mediated cytolysis [11].

Inflammatory cytokines such as IFN-γ and TNF-α increase the expression of Fas, a TNF-receptor family member, during GVHD [38]. FasL expression on donor T cells is also increased during GVHD [39]. Elevated serum levels of soluble FasL and Fas have also been observed in some patients with acute GVHD [40]. FasL-defective donor T cells cause markedly reduced experimental GVHD in liver, skin, and lymphoid organs [41]. The Fas/FasL pathway is particularly important in hepatic GVHD [42].

Inflammatory effectors

A central role for inflammatory cytokines, the effector phase, in acute GVHD was confirmed by murine studies using bone marrow chimeras in which either MHC class I or class II alloantigens were not expressed on target epithelium but on APCs alone [5]. GVHD target organ injury was induced in these chimeras even in the absence of epithelial alloantigens, and mortality and target organ injury were prevented by the neutralization of TNF-α and IL-1.

Severe GVHD is associated with high levels of TNF-α messenger RNA in target tissues [43]. Target organ damage could be inhibited by infusion of anti-TNF-α mAbs, and mortality could be reduced by the administration of the soluble form of the TNF-α receptor [2]. Extensive experimental data further suggest that TNF-α is an important effector molecule of GVHD [5,43,44].

Secretion of IL-1 appears to occur predominantly during the effector phase of GVHD in the spleen and skin, two major GVHD target organs. However, use of IL-1 receptor antagonist shortly after conditioning was not successful in preventing acute GVHD in a randomized trial [45]. It is likely that redundancy of inflammatory pathways bypasses the direct inhibition of IL-1 or TNF-α, reducing the clinical benefit of targeting single cytokines to prevent clinical acute GVHD.

Finally, macrophages can also produce significant amounts of NO that contribute to target tissue damage and to GVHD-induced immunosuppression [24]. NO inhibits the proliferation of epithelial stem cells in the gut and skin, and the development of GVHD is preceded by an increase in NO oxidation products in the serum [46].

Toll-like receptors (TLRs) and innate immunity

TLRs on primed mononuclear cells may be stimulated to secrete cytokines by LPS and PAMPs that leak through an intestinal mucosa damaged by conditioning regimens during step 1. The simultaneous release of DAMPs from conditioning- related injury also probably intensifies the inflammatory signals. Damage to the GI tract during the effector phase can lead to a positive feedback loop wherein increased translocation results in further cytokine production and progressive intestinal injury, propagating the “cytokine storm” characteristic of acute GVHD. Evidence suggests that damage to the GI tract during acute GVHD plays a major role in the amplification of systemic disease [47].

This conceptual framework underscores the role of the GI microbiome in the development of acute GVHD [48]. LPS is a major structural component of Gram-negative bacteria and is a potent stimulator of cellular activation and can elicit a broad range of inflammatory responses. In particular, LPS may stimulate gut-associated lymphocytes and macrophages. Following allogeneic HCT, LPS accumulates in both the liver and spleen of animals with GVHD prior to its appearance in the systemic circulation. Elevated serum levels of LPS have been shown to correlate directly with the degree of intestinal histopathology occurring after allogeneic HCT [49]. Death from GVHD can be prevented if transplanted mice are given antibiotics to decontaminate the gut or housed in a germ-free environment [50]. Molecules that act as competitive inhibitors to LPS at the cell surface and block nuclear factor-kappa B (NFκB) activation and nuclear translocation block the biologic response to LPS and result in decreased inflammatory cytokine release and reduced GVHD severity while preserving potent graft-versus-leukemia effects (GVL) and improved leukemia-free survival [51].

Traffic of cellular effectors

Regulation of effector cell migration into GVHD target tissues occurs in a complex milieu of chemotactic signals that recruit effector cells, such as T cells, neutrophils, and monocytes [52]. Upon stimulation, T cells can rapidly switch chemokine receptor expression, acquiring new migratory capacity [53]. Macrophage inhibitory protein-1 alpha recruits CCR5$^+$CD8$^+$ T cells into the liver, lung, and spleen during GVHD [54], and levels of several chemokines are elevated in GVHD-associated lung injury [55]. After T-cell activation by DCs, a profile of adhesion molecules and chemokine receptors direct the cells back to the organ of DC origin. For example, activated T cells that leave a lymph node in the skin express cutaneous lymphocyte antigen [56]. T cells expressing cutaneous lymphocyte antigen home only to the skin, where they may mediate cutaneous GVHD. The addition of the

CCR5 antagonist maraviroc to standard GVHD prophylaxis dramatically reduced GI GVHD in a small phase II study [57]. Similarly, α4β7 is necessary for homing to GI tract- and gut-associated lymphoid tissues [58]. Thus, cells bearing the appropriate cell surface adhesion receptors for the GI tract (e.g. LPAM-1) and chemokine receptors (e.g. CCR25) undergo firm adhesion followed by transmigration through the blood vessel into the appropriate organ. Mesenchymal stromal cells also appear to reduce severe GI GVHD, but their mechanism of action remains unclear [59].

GVHD prevention: from animal models to clinical practice

The development of strategies for GVHD prophylaxis and therapy has suffered from a limited understanding of the underlying pathophysiology of GVHD. This conceptual limitation led to approaches that were based on an "oncologic" model of GVHD, i.e. the notion that since GVHD is dangerous and life threatening, management requires the utilization of high-dose immunosuppressant regimens. High doses of multiple immunosuppressive agents have been used much like we use combination chemotherapy to treat malignancies. Although there is often reasonable control of the clinical manifestations of GVHD, this "shotgun" approach lacks elegance and is usually associated with opportunistic infections, lymphoproliferative disorders, or relapse of the underlying malignancy. Indeed, it is often infection while GVHD is in remission that results in mortality. The objective should be to reduce the non-specific tissue damage associated with GVHD while allowing effective immunologic recovery.

The three-phase model described above can be simply summarized. GVHD is an exaggerated and dysregulated response of a normal immune system (that of the donor) to tissue damage that is intrinsic to transplantation. The donor's immune system reacts as if there is a massive and uncontrolled infection, and its efforts to deal with this injury result in the clinical manifestations of GVHD. It is possible that the tissue injury intrinsic to the administration of high-dose chemoradiotherapy initiates the breakdown of mucosal barriers, allowing LPS and PAMPs into the tissues and also DAMPs that stimulate the inflammasome. TLRs on DCs bind to endotoxin and activate signal transduction pathways that lead to DC maturation and induce inflammation [60]. The upregulation of costimulatory molecules, MHC molecules, adhesion molecules, cytokines, chemokines, prostanoids, and other inflammatory mediators prime and trigger the attack on target tissues, fueling the fire. Thus, it is likely that components of cytokine storm [61], the danger hypothesis [12], and more traditional notions of adaptive and innate immunity [62] all apply. Moreover, with our improved understanding of inhibitory pathways that regulate and suppress inflammation, it may be possible to enhance regulatory mechanisms rather than attempt to engender immunologic paralysis. Some examples of the targeting of the various stages of GVHD are shown in Table 13.1.

Table 13.1 Examples of approaches to prevent or treat GVHD

Step	Potential intervention[a]
Step 1: Effects of conditioning	Reduced intensity conditioning Use of mAbs or other non-cytotoxic agents
Step 2: Donor T-cell activation and cytokine production	Gut decontamination and antiviral prophylaxis Corticosteroids Calcineurin inhibitors Mycophenolate, methotrexate, cyclophosphamide MTOR inhibition (sirolimus) Proteasome inhibition (bortezomib) Inhibition of costimulation Clinical use of Treg cell (low-dose IL-2) HDAC inhibitors (vorinostat) Extracorporeal photopheresis
Step 3: Cellular and inflammatory effectors	T-cell depletion (in vivo and in vitro) Cytokine inhibition (etanercept, infliximab, anti-BAFF) CCR5 inhibition (maraviroc) Tyrosine kinase inhibitors (e.g., PDGFRα inhibition)

[a] Many of the interventions listed span steps 2 and 3.

Step 1: reduced-intensity conditioning regimens

The three cardinal organs affected by GVHD are the skin, intestinal tract, and liver. The common thread would seem to be exposure to the environment. Skin and gut have very obvious barrier functions and a well-developed reticuloendothelial system. DCs resident in these organs present antigens to naïve T cells, which then have alterations in cell surface characteristics that cause them to return to the organ that originated the specific DC. Similarly, the liver is the first line of defense downstream of the gut. One would expect the lung to be a similar target; however, its less intense exposure to organisms, particularly Gram-negative rods, probably reduces its primacy as a target organ. Nevertheless, recent studies clearly demonstrate pulmonary injury that is likely to reflect GVHD. All of these organs are rich in DCs, a probable prerequisite for generating the injurious cytokines in addition to directing the attack of the adaptive immune system. They are all subject to injury from conditioning, and breaches of the barrier will allow organisms or endotoxin into the circulation.

One prediction of this model is that less-intense conditioning regimens would be associated with less GVHD. This effect was initially observed after donor lymphocyte infusions. The T cells were administered *without* pharmacologic GVHD prophylaxis, and the resultant GVHD was less frequent and severe than would be expected in the absence of immunosuppressive drugs. It could be inferred that reduced-intensity conditioning regimens might similarly be associated with less severe GVHD, both through less cellular injury per se and through a reduction in endotoxin exposure by virtue of less mucosal injury. Available data suggest that the rate of GVHD after reduced-intensity conditioning regimens is similar to the rate seen after conventional dose conditioning [63]. Interestingly, the onset of GVHD is delayed and an overlap syndrome of acute and chronic graft-versus-host disease (cGVHD) is more prevalent. This observation suggests that the initial tissue injury of high-dose regimens speeds the development of GVHD and reduced-intensity procedures seem to have little effect on cGVHD. Thus, while data on both reducing colonization with bacteria and reducing tissue injury with less-intense regimens are suggestive and support the basic concepts described above, the effect is insufficient to control GVHD adequately in human transplantation.

Step 2: modulation of donor T cells

Reduced T-cell numbers

The advent of monoclonal technology in the 1980s led to the logical conclusion that if a pharmacologic reduction in T-cell numbers could partially control GVHD, albeit at the risk of drug-induced toxicity, then eliminating the cells with mAbs, immunotoxins, lectins, CD34 columns, or physical techniques might be more effective [64]. Furthermore, the ability to identify and target specific T-cell subsets opened up the possibility that the graft could be engineered to control GVHD while allowing immunologic recovery as well as GVL. A typical unmanipulated marrow transplant entails the infusion of about 10^7 T cells/kg of recipient. Establishment of a clear dose–response relationship is difficult since the risk of acute GVHD depends on factors beyond simple dosing, for example, minor histocompatibility disparities, virus exposure, disease and stage, donor age, and recipient age. Studies of counterflow elutriation showed that 10^6 T cells/kg plus cyclosporine (CSP) resulted in a GVHD rate similar to that of CSP alone, but 5×10^5 T cells/kg plus CSP resulted in an overall rate of 22%, and only limited skin involvement was observed [65]. After lectin depletion of T cells in the absence of supplemental immunosuppression, a T-cell dose of around 10^5/kg was associated with complete control of GVHD [66]. More recently, the combination of very high stem cell numbers and CD3 T-cell numbers of less than 3×10^4/kg allowed haploidentical transplantation without GVHD [67].

Global T-cell depletion (TCD) using a broad panel of mAbs has largely been abandoned because of the risk of graft failure [68]. However, it is clear that even depletion of T-cell subsets must be undertaken with caution. Depletion of $CD4^+$ or $CD8^+$ T cells alone can be associated with a high graft failure rate [69]. However, depletion of $CD5^+$ or $CD6^+$ T cells seems to be associated with a low graft failure rate [70]. The presumption is that radioresistant T cells that survive the initial conditioning are responsible for graft rejection. When the stem-cell source is rich in T cells, the GVH reaction will further reduce the residual population capable of alloreactivity, thus decreasing graft rejection. To some extent, the higher graft failure rates may be controlled by increasing the intensity of the conditioning regimen [71], adding back T cells [65], or with additional immunosuppressants [72]. Additional problems associated with TCD include a higher incidence of Epstein–Barr virus-induced lymphoproliferative disorders, loss of the GVL with a consequent increase in relapses, and slower immunologic recovery due to reduced passive transfer of immunocompetent donor T cells. These concerns also have been approached by increasing the conditioning intensity, delayed T-cell add-back [73], rituximab [74], or the infusion of specific T-cell lines [75]. However, in no case has there been an improvement in survival that can be definitively attributed to TCD. A large multicenter study of unrelated donor HCT similarly showed no improvement in outcomes after TCD [76]. Although not confirmed in a randomized trial, in early-remission acute leukemia, CD34 selection and an intensified conditioning regimen appear to result in similar survival to conventional GVHD prophylaxis with less cGVHD [77,78]. Both antithymocyte globulin (ATG) and alemtuzumab deplete T cells in vivo. ATG appeared in some studies to reduce both acute and cGVHD [79]. Alemtuzumab also reduces acute and cGVHD but at the expense of high relapse rates and graft failure [80]. An observational database analysis of the role of in vivo TCD demonstrated inferior outcomes in reduced-intensity conditioning regimens [81]. However, a randomized trial in high-intensity conditioning HCT reported similar survival but substantially reduced cGVHD in patients treated with ATG [82,83]. Hence the role of TCD, whether in vivo or in vitro, remains to be fully elucidated.

Reduced T-cell activation

Calcineurin inhibition with either CSP or tacrolimus is the current standard for GVHD prevention. Both drugs bind to immunophilins: CSP binds cyclophilin and tacrolimus binds FKBP12. The complex of drug and binding protein, calcium, calmodulin, and calcineurin is then formed, and the phosphatase activity of calcineurin is inhibited. This effect may prevent the dephosphorylation and translocation of nuclear factor of activated T cells (NF-AT), a nuclear component thought to initiate gene transcription for the formation of lymphokines such as IL-2 and IFN-γ. The net result is the inhibition of T-cell activation. As a single agent, CSP was about as effective as methotrexate (MTX) [84]. However, in combination with MTX, there was a significant reduction in the incidence of GVHD and an improvement in survival [85]. Subsequent trials of tacrolimus and MTX compared with CSP and MTX showed no advantage for either combination [86]. DCs appear to be critical to the development of acute GVHD [8]; therefore, interference with DC function would probably prevent GVHD. The goal would be to inhibit function selectively or temporarily until transplanted DC precursors had engrafted and become functional. Alemtuzumab is a promiscuous antibody, targeting B cells, T cells, monocytes, and DCs. When the drug was administered prior to HCT, host DCs were selectively depleted and the donor DCs repopulated the recipient [87]. These observations are difficult to separate from concomitant TCD, but they may be consistent with the theme that facilitation of DC turnover may ameliorate GVHD.

Reduced T-cell proliferation

The first generally prescribed GVHD preventive regimen was the administration of intermittent low-dose MTX as developed in a dog model by Thomas and colleagues [88]. Another regimen developed by Santos et al., based on cyclophosphamide (CTX) [89], was never widely adopted. The principle of this approach is to administer a cell-cycle-specific chemotherapeutic agent intermittently immediately after the transplant, when the T cells will have started to divide after exposure to allogeneic antigens. This was an effective approach compared with no prophylaxis [90]; however, GVHD control was incomplete. Subsequently, the addition of ATG or prednisone, or both, resulted in an incremental improvement in the GVHD rate but no improvement in survival [91]. Ultimately, the course of MTX was abbreviated and combined with CSP or tacrolimus, resulting in the current gold standard for GVHD prevention. More recently, it has been shown that high-dose CTX can be substituted for MTX after stem-cell infusion. Stem cells are insensitive to CTX but activated T cells are eradicated. This approach seems to be effective in combination with tacrolimus and microphenolate mofetil (MMF) and appears to facilitate HCT across HLA barriers [92]. The use of CTX may also reduce cGVHD [92,93].

MMF is another useful agent that may prevent GVHD but with less mucositis and myelotoxicity than MTX. It is the prodrug of mycophenolic acid (MPA), a selective inhibitor of inosine monophosphate dehydrogenase, and inhibits the de novo pathway of guanosine nucleotide synthesis. Since T-lymphocytes are dependent on the de novo synthesis of purines, MPA inhibits the proliferative responses of T cells to allogeneic stimulation. Myeloid and mucosal cells can utilize salvage pathways, so the drug is less toxic to mucosa and myeloid recovery. MPA also prevents the glycosylation of glycoproteins that are involved in adhesion to endothelium and may reduce the recruitment of leukocytes into inflammatory sites. MPA does not inhibit the activation of T cells as such, but blocks the coupling of activation to DNA synthesis and proliferation [94]. Many trials of the combination of MMF with CSP or tacrolimus have shown reliable but

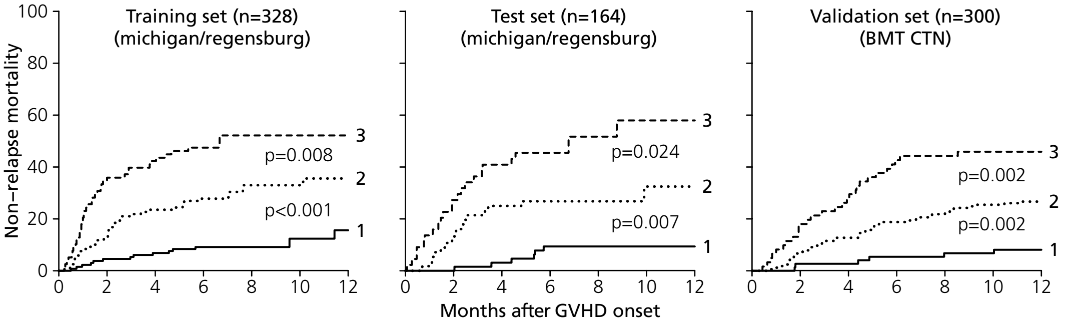

Figure 13.2 Non-relapse mortality (NRM) by Ann Arbor score at GVHD onset. Cumulative incidence of non-relapse mortality for each Ann Arbor score of 1, 2, or 3 is shown for the 328-patient training set from the Universities of Michigan and Regensburg [1 (solid) vs 2 (dots), $p < 0.001$; 2 vs 3 (dashes), $p = 0.008$], the 164-patient test set (1 vs 2, $p = 0.007$; 2 vs 3, $p = 0.02$), and the 300-patient multicenter validation set from the Bone Marrow Transplant Clinical Trials Network (Ann Arbor 1 vs 2, $p = 0.002$; 2 vs 3, $p = 0.002$). Source: adapted from Levine et al. 2012 [100].

incomplete control of GVHD when used in conjunction with a calcineurin inhibitor.

Sirolimus is a macrocyclic lactone that is similar in structure to tacrolimus and CSP. All three drugs bind to immunophilins; however, sirolimus complexed with FKBP12 inhibits T-cell proliferation by interfering with signal transduction and cell-cycle progression. Sirolimus affects lymphocyte activation at a later stage than either CSP or tacrolimus. The sirolimus–FKBP12 complex binds to mammalian target of rapamycin (MTOR), which blocks IL-2-mediated signal transduction pathways that prevent G_1/S phase transition. The drug has similar effects on the proliferation of T cells induced by IL-2, IL-4, IL-7, IL-12, and IL-15. Interestingly, it may also interfere with costimulation [95] by inhibiting CD28-mediated blocking of inhibitor of NF-κB and translocation of c-Rel to the nucleus [96]. A potential advantage of sirolimus is that it inhibits Treg cell less than calcineurin inhibitors. Since it acts through a separate mechanism, sirolimus is synergistic with both tacrolimus and CSP. Since the sirolimus–MTOR complex does not bind to calcineurin, sirolimus also is free of nephrotoxicity and neurotoxicity, making combination therapy appealing. The proteasome inhibitor bortezomib has useful effects on cytokine signaling and NF-κB activation. It can deplete alloreactive T cells while sparing Treg cell. It inhibits APCs by interfering with TLR4 activation, and it reduces T-cell differentiation induced by IL-6 [97].

Step 3: blockade of inflammatory stimulation and effectors

Reduced exposure to organisms

Another hypothesis that flows from this model is that reduction of intestinal colonization with bacteria could prevent GVHD. The first indication that elimination of exposure to microorganisms could prevent GVHD was in germ-free experiments in mice, where GVHD was not observed until the mice were colonized with Gram-negative organisms. Later, gut decontamination and use of a laminar airflow environment were associated with less GVHD and better survival in patients with severe aplastic anemia. Similarly, studies of intestinal decontamination in patients with malignancies have shown less GVHD in some but not all studies. However, despite the power of a large number of patients in registry analyses [98], it is possible that the heterogeneity of care in the large number of participating centers obscured an important effect. Viral infections, particularly herpes viruses, may also be associated with GVHD.

Blockade of effectors

Titers of several inflammatory cytokines can be used as both biomarkers for acute GVHD and to suggest targets for therapy. Recent studies have identified Regenerative 3 alpha as biomarkers specific for GVHD of the GI tract, the target organ that is least responsive to therapy [99]. Also, a new Ann Arbor scoring system uses a panel of three bioarkers [TNFR1, Regenerative 3 alpha and ST2 (a soluble IL-33 receptor)] to assign patients to a risk category at the onset of GVHD has been validated in a multicenter setting to predict non-relapse mortality, allowing for tailored therapy from the onset of symptoms (Figure 13.2) [100].Therapy directed at TNF-α produced partial responses either as therapy for steroid-resistant GVHD or as prophylaxis [101]. However, as noted above for IL-1 inhibition, redundant pathways may preclude effective therapy directed at a single cytokine. Blockade of chemokines may prevent the recruitment, localization, and activation of lymphocytes during GVHD. Prevention of lymphocyte entry into secondary lymphoid organs, acquisition of appropriate homing and adhesion molecules, or modification of their entry into target tissues could all reduce GVHD [102].

Chronic GVHD

It is important to recognize that cGVHD was originally defined temporally rather than clinically or pathophysiologically. The initial clinical reports of cGVHD used descriptions of clinical problems occurring at least 150 days after HCT [103]. By convention, many transplant clinicians and scientists use day 100 after hematopoietic cell infusion as a convenient divider between acute and cGVHD. However, it should be recognized that acute manifestations of GVHD may occur after day 100, and problems typically associated with cGVHD may occur before day 100. Therefore, it is preferable to consider the symptoms and signs per se rather than the timing of the onset of clinical findings. The National Institutes of Health consensus conference on cGVHD recognizes four categories of GVHD (Table 13.2) [104] (see Chapter 85).

The dearth of animal models that reproduce the critical aspects of cGVHD has limited our ability to address the pathophysiology of this complication, although a more recent model seems to be more representative of the human disease [105]. cGVHD can be considered to have both alloimmune and autoimmune components [105,106]. Indeed, autoantibody production is commonly observed after HCT, and some of the clinical manifestations of cGVHD are similar to those of scleroderma, lichen planus, and other autoimmune

Table 13.2 National Institutes of Health consensus conference categories of graft-versus-host disease

	Time	Acute features	Chronic features
Acute			
Classic acute	<100 days	Yes	No
Persistent, recurrent, or late onset	≥100 days	Yes	No
Chronic			
Classic chronic	No limit	No	Yes
Overlap	No limit	Yes	Yes

diseases. T cells from animals with cGVHD produce patterns of cytokines, such as IL-4, or IFN-α in the absence of IL-2 that are consistent with cGVHD reflecting in part Th2 T cell-induced injury [107]. There is often an eosinophilia as an early manifestation of cGVHD, further supporting the notion that cells with a Th2 phenotype are important mediators of this problem [108].

One mechanism to induce autoimmune attack might be failure of normal regulatory mechanisms in the setting of thymic damage or immunosuppressants, or both. Patients with cGVHD have fewer circulating Treg cell, thymic generation of naive Treg cell is impaired, and reconstituting Treg cell had a predominantly activated/memory phenotype. In response to CD4$^+$ lymphopenia after HCT, Treg cell proliferate more than conventional T cells, but with increased susceptibility to Fas-mediated apoptosis. Treg telomere length is shorter whereas Treg telomerase activity and expression of BCL-2 were each inversely associated with severity of cGVHD [109,110]. Failure of Treg cell results in autoimmune phenomena increasingly implicated in both acute and cGVHD [111]. Moreover, Treg cell are implicated in preventing autoantibody production [112].

Another explanation of autoimmunity may be that the massive apoptosis of T cells early in acute GVHD overwhelms the macrophage/DC system, resulting in autoantigen presentation [113]. The autoreactive cells of cGVHD are associated with a damaged thymus, which may be injured by acute GVHD or by the conditioning regimen, or be subject to age-related involution and atrophy. Therefore, the normal ability of the thymus to delete autoreactive T cells and to induce tolerance may be impaired.

Finally, data are accumulating to support the concept that B cells contribute to cGVHD. In a mouse model of cGVHD, fibrosis was demonstrated in the lung and liver and was associated with CD4$^+$ T cells and B220$^+$ B-cell infiltration and alloantibody deposition. Donor bone marrow obtained from mice incapable of secreting IgG alloantibody resulted in less cGVHD, and blockade of germinal center formation suppressed cGVHD [106]. The anti-CD20 mAb rituximab has been used clinically to treat severe autoimmune disorders including autoimmune hemolytic anemia and idiopathic thrombocytopenic purpura, and now several series indicate that anti-B-cell therapy is an interesting approach to treating cGVHD [114]. Alloantibodies can facilitate the cross-presentation of antigens to effector T cells, thereby amplifying T-cell responses to mHAs [115]. Donor B cells are capable of generating antibody responses specific for recipient mHAs, and cGVHD is significantly associated with the presence of high-titer mHA antibodies [116]. The presence of antibodies to mHAs also suggests that donor B cells have productive interactions with donor CD4 cells [116]. B cells can act directly as APCs in their ability to process and present limiting amounts of antigen for presentation to T cells. The presence of alloantibodies and high plasma B cell-activating factor (BAFF) levels in patients with cGVHD suggest that B cells play a role in disease pathogenesis. BAFF promotes survival and differentiation of activated B cells. Patients with cGVHD have significantly higher BAFF/B-cell ratios than patients without cGVHD or healthy donors. High BAFF concentrations are associated with activated B cells capable of IgG production without requiring additional antigen stimulation [117,118]. It has also recently been demonstrated in female-to-male transplants that donor-derived T cells can be isolated that recognize donor and recipient nonpolymorphic X chromosome-encoded proteins (e.g. DBX) [119] and also the production of antibodies to epitopes on the polymorphic Y chromosome-encoded proteins, DBY [116]. In this context, the allogeneic reaction may inactivate donor APCs that are essential for establishing cGVHD, through cross-presentation of host antigens to donor T cells [120]. Thus, during the course of cGVHD, a loss of tolerance to self may result in donor T-cell recognition of both self- and recipient antigens [121].

Conclusion

Complications of HCT, particularly GVHD, remain major barriers to the wider application of allogeneic HCT for a variety of diseases. Recent advances in the understanding of cytokine networks, and also the direct mediators of cellular cytotoxicity, have led to improved understanding of this complex disease process. GVHD can be considered to be an exaggerated, undesirable manifestation of a normal inflammatory mechanism in which donor lymphocytes encounter foreign antigens in a milieu that fosters inflammation. Tissue injury related to the conditioning regimen or infection is then amplified by direct cytotoxicity via perforin/granzyme and Fas/FasL pathways, through direct cytokine-induced damage, and by recruitment of secondary effectors such as granulocytes and monocytes. Thymic injury and loss of Treg function may enhance donor cell recognition of histocompatibility antigens by both T and B cells. Moreover, the production of auto- and alloantibodies may further result in tissue injury in addition to enhancing T-cell-related cellular injury. The net effects of this complex system are the severe inflammatory manifestations that we recognize as clinical GVHD.

CHAPTER 14

Immune Regulation in Hematopoietic Cell Transplantation

Robert S. Negrin[1] **and Jerome Ritz**[2]

[1] Stanford University, Stanford, CA, USA

[2] Harvard Medical School, Dana-Farber Cancer Institute, Boston, MA, USA

Introduction

Immune regulation is critical to health and disease and many disease states are caused or exacerbated by ineffective or excessive immune responses. Nowhere is this clearer than following allogeneic hematopoietic cell transplantation (HCT), where functional immune reactions can eradicate residual disease such as leukemia and other hematologic malignancies termed the graft-versus-tumor (GVT) effect, whereas dysfunctional immune responses can result in immune-mediated destruction of host tissues in graft-versus-host disease (GVHD). A deeper understanding and manipulation of immune regulatory mechanisms to control dysregulated immune responses have enormous potential for improving outcomes following allogeneic HCT and also could be extended to a variety of other fields, including induction of solid organ transplantation tolerance and treatment of autoimmune disorders. Therefore, the study of the mechanisms of immune regulation is of critical importance in many clinical settings. In this chapter, we review new approaches to the modulation of immune regulatory mechanisms to reduce GVHD risk and enhance immune recovery in allogeneic HCT. We focus on the cellular aspects of immune regulation, and strategies to modulate various cell populations that play a role in immune regulation for clinical benefit.

In the context of allogeneic HCT, it is important to note that all aspects of immune regulation must be re-established as the recipient's immune system is replaced by immune cells from the stem-cell donor. Critically, the transition from host to donor hematopoiesis often occurs rapidly as effector cells in the stem-cell graft recognize and respond to widely expressed immunogenic alloantigens in the recipient. This is a unique situation, which sets allogeneic stem-cell transplantation apart from other disorders of immune regulation and also provides unique opportunities for establishing the role of different immune regulatory cells and the mechanisms that these cells utilize in the establishment of immune tolerance. This unique setting also provides the opportunity to develop novel approaches to modulate this process for clinical benefit.

Regulation of immune function is a complex process involving a variety of important mechanisms. Given the critical importance of these mechanisms in maintaining self-tolerance and preventing autoimmunity, these mechanisms are often partially redundant and context dependent. Critical to our understanding is the compartmentalization of immune responses that is characteristic of response to infection and tissue injury. In the setting of allogeneic HCT, this compartmentalization is lost as immune effector cells, primarily donor T cells, respond to recipient alloantigens resulting in GVHD pathophysiology. Through the use of murine models, it has been determined that there are multiple priming sites for T-cell activation resulting in proliferation of alloreactive T cells present in the donor inoculum which become activated, expand, and infiltrate GVHD target tissues, primarily the gastrointestinal tract, skin, and liver [1,2]. At these sites, donor T cells cause tissue damage, resulting in organ dysfunction and increased risk of infection. Control of normal immune reactions also involves both pro- and anti-inflammatory cytokines that are critically important to immune regulation [3]. In addition, various cellular populations have been identified that play important roles in immune regulation termed regulatory T cells (Treg cells). Further work has also identified the potential for other regulatory cell populations such as natural killer T (NKT) cells, myeloid derived suppressor cells (MDSCs), B cells, mesenchymal stromal cells (MSCs), and antigen-presenting cells (APCs). Owing to their potential clinical applicability, we focus on cellular populations of regulatory cells including Treg cells, NKT cells, and MSCs and approaches to modulate these populations in vitro and in vivo. Chapter 12 also describes many of the properties of these different cell populations and their proposed roles in tolerance induction to solid organ transplantation.

Regulatory cell populations

A large body of evidence has demonstrated that a number of different cell populations are capable of controlling immune responses (see Table 14.1). The concept of suppressor cells was initially identified through in vitro assays measuring suppression of the mixed lymphocyte reaction (MLR). In this assay, irradiated stimulator cells are admixed with responder cells followed by the addition of [^{3}H]thymidine. The responding cells proliferate and incorporate [^{3}H]thymidine that can be quantified by harvesting the cells and measuring the incorporation of radioactivity. The addition of different cell populations capable of suppressing the MLR was critical to the identification of specific regulatory cell populations and remains a key in vitro assay for measuring the functional activity of regulatory cells. A defined population of CD4$^+$ T cells that co-expressed the interleukin-2 (IL-2) receptor α chain (CD25) was found to suppress the MLR and these cells were termed regulatory

Table 14.1 Immune regulatory populations in allogeneic stem-cell transplantation

Population	Characteristic phenotype	Additional surface markers
CD4 regulatory T cells (CD4 Treg cells)	$CD3^+$ $CD4^+$ $FoxP3^+$ $CD25^+$ $CD127^{low}$	$CD152(CTLA\text{-}4)^+$ $GITR^+$ $CD223(LAG3)^+$
Natural killer T cells (NKT cells)	$CD3^+$ $CD56^+$	$CD161^+$ $V\alpha24i^+$ $CD4^{+/-}$ $CD8^{+/-}$
Mesenchymal stromal cells (MSCs)	$CD73^+$ $CD90^+$ $CD105^+$ $CD34^-$ $CD45^-$ $H\ LA\text{-}DR^-$	$CD11b^-$ $CD14^-$ $CD19^-$ $CD29^+$ $CD44^+$ $CD71^+$ $CD79a^-$ $CD166^+$
Myeloid-derived suppressor cells (MDSCs)	$CD11b^+$ $CD14^-$ $CD15^+$ $CD33^+$	$CD66b^+$ $CD124^+$ $VEGFR1^+$ $HLA\text{-}DR^-$

T cells (Treg cells) [4,5]. Later, it was determined that these Treg cells expressed the forkhead box P3 (FoxP3) transcription factor which is characteristic of naturally occurring Treg (nTreg) cells [6]. Interestingly, introduction of FoxP3 into conventional T cells resulted in acquisition of functional regulatory properties, establishing the central role for FoxP3 expression in Treg function. Further, genetic mutations that inactivate FoxP3 cause severe autoimmune disease in both animal models and in humans [7]. Although the majority of Treg cells are derived from the thymus, it has also been shown that they can be generated in vivo through the conversion of conventional CD4 T cells into Treg cells. These cells, termed induced Treg (iTreg) cells, acquire regulatory functions coincident with the expression of FoxP3 and maintain regulatory function as long as FoxP3 gene is expressed [8–10].

Although the exact mechanisms by which Treg cells suppress the MLR and autoimmune responses in vivo have not been fully elucidated, it is recognized that cell contact is important and a variety of different cytokines and cell-surface molecules play important roles [11]. It is also evident that Treg cells are capable of suppressing a variety of immune cells in addition to CD4 and CD8 T cells. These include dendritic cells, B cells, macrophages, natural killer (NK) cells and NKT cells [11,12].

The role of natural regulatory T cells in GVHD suppression

The recognized ability of nTreg cells to suppress autoimmunity led to several studies that examined the potential role of these regulatory cells in GVHD pathophysiology. Murine models have been essential for demonstrating the biological function of regulatory cell populations, initially focusing on nTreg cells and more recently on a variety of other cell populations. Initial studies focused on depleting $CD25^+$ T cells from the donor splenocyte inoculum to study the role of these cells in animal models of GVHD. These studies demonstrated that depletion of $CD25^+$ cells, typically approximately 10% of the $CD4^+$ T cells, resulted in more potent induction of GVHD compared with infusion of undepleted donor T cells [13]. Using different animal models across both major and minor histocompatibility mismatches, it was found that the addition of nTreg cells initially in a 1:1 ratio with conventional CD4 and CD8 cells resulted in suppression of GVHD [13–16]. Typically, these studies were performed by adoptively transferring highly purified $CD4^+CD25^+FoxP3^+$ nTreg and Tcon cell populations the day after transplantation with bone marrow-derived cells with or without T cell depletion to result in hematopoietic recovery. Similar studies were performed with human cells, assessing the ability of CD25-depleted stem cells to cause xenogeneic GVHD following transplantation into immune-deficient murine recipients [17]. These studies firmly demonstrated the potential for nTreg suppression of GVHD and provided the initial motivation for translation of these findings into the clinic. Further work demonstrated that nTreg cells selectively suppress conventional T (Tcon) cells, which actively replicate during GVHD induction. In these studies, it was also observed that nTreg cells rapidly proliferate in the allogeneic setting, especially in irradiated recipients, which is contrary to what was observed in vitro, where Treg cells typically do not expand in the MLR [18]. This finding suggested that the addition of Treg prior to Tcon cells would allow the former to proliferate and expand in vivo and this could be utilized to decrease the dose of Treg cells required for effective GVHD suppression. Since nTreg cells are relatively rare, obtaining sufficient numbers of cells for in vivo function is difficult, hence in vivo proliferation may be critically important to translate these concepts to the clinic. In these studies, addition of the nTreg cells 2 days prior to Tcon cells allowed for the reduction in nTreg cells by 5–10-fold, while still maintaining suppressive function of GVHD [18]. An alternative approach that is also clinically viable has been to expand the nTreg population ex vivo prior to adoptive therapy (see below).

An important component of these studies has been to examine the impact of nTreg cells on GVT reactions. In several reports, it was demonstrated that GVT reactions were preserved in some but not all tumor models [4,15,19]. To explain how nTreg cells can selectively suppress GVHD and not affect GVT, it was determined that nTreg cells selectively suppress Tcon-cell proliferation in the setting of allogeneic HCT, thereby suppressing the pathologic impact of Tcon cells in inducing GVHD. However, where there is a high T-cell precursor frequency for alloantigens, T-cell proliferation is not essential for GVT responses because the number of T cells capable of recognizing these alloantigens is relatively high and sufficient for tumor eradication. Therefore, suppression of Tcon-cell proliferation results in effective suppression of GVHD, yet still allows for GVT, especially in the setting where there is a relatively low tumor burden, as is typical in animal models, and also clinical treatments for patients undergoing allogeneic HCT due to the impact of the preparative regimen on tumor burden. The critical role of perforin and granzymes was essential for GVT function. It remains to be determined whether these predictions will hold true in clinical transplantation; however, the results of these in vivo models provided further encouragement for the translation of these concepts to the clinic.

Another concern was whether infusion or expansion of nTreg cells in vivo would result in severe global immunosuppression in recipients. In several studies, it was demonstrated that animals that received nTreg cells actually had improved immune reconstitution, as demonstrated by recovery of immune effector cell populations, and also following challenge with infectious agents such as murine cytomegalovirus (mCMV) [4,20,21]. These findings were thought to be due to the ability of the nTreg cells to suppress GVHD-induced tissue injury to secondary lymphoid tissues such as lymph nodes and thymus, allowing for more effective immune recovery in the post-transplant setting. Taken together, these studies set the stage for various approaches to expand or enhance selectively nTreg cells after allogeneic HCT in clinical trials that are detailed below.

Ex vivo expansion of Treg cells

Owing to the relative paucity of nTreg cells, it was speculated that expansion of this cell population would be important for clinical translation. Several groups have demonstrated that nTreg cells can be expanded in vitro in both murine and human systems [14,22–24]. To induce expansion, activation is required, typically through

CD3/CD28 stimulation in the presence of TGFβ and APCs. With this approach, significant expansion of nTreg cells can be achieved over a 14–21-day culture period, resulting in relatively large populations of cells, which can then be utilized for studies of in vivo biological function. Similar expansion of nTreg cells has been accomplished in humans. However, in all of these studies, a major limitation has been that although Treg cells proliferate in vitro, conventional T cells often outgrow these cultures and appear to expand preferentially [25]. A variety of strategies have been utilized to suppress Tcon-cell proliferation, including the use of rapamycin to suppress selectively Tcon cells and exhaustive depletion of Tcon cells from the Treg-cell inoculum [26]. This strategy has also been extended to the clinic, as described below. Isolation of $CD45RA^+CD4^+CD25^+$ cells prior to expansion has also been shown to result in robust expansion of suppressive populations of polyclonal Treg cells [27]. Other approaches have also resulted in robust Treg-cell expansion in clinically relevant strategies [28].

Critical requirements for Treg-cell function

Although many aspects of Treg-cell function, regulation, and homeostasis have not been fully elucidated, a large number of studies in many laboratories have greatly improved our understanding of the biology of Treg cells and the important role that these cells play in regulating immune responses in vivo [8–11]. For example, several studies demonstrating that expression of CD62L, a molecule required for lymph node entry, is essential for in vivo Treg-cell function, have established that nodal migration is required for in vivo function of these cells. These studies demonstrated that ~50% of nTreg cells express CD62L whereas 50% typically are $CD62L^-$. Both cell populations suppress the MLR yet only the $CD62L^+$ nTreg cells function in vivo [29,30]. Many other studies have been performed to identify the essential molecules required for nTreg-cell function in GVHD models [31,32]. Among these molecules, several studies have identified PD-1 and PD-L1 as playing important roles in the interaction of Treg cells with effector T cells [33,34]. Although it is not yet clear how Treg cells function in controlling GVHD reactions and also other immune responses, several cytokines, including IL-10, TGF-β, FLT3-ligand, IFNγ, and IL-35 have been implicated [35–40]. Treg cells are not able to secrete IL-2, but the constitutive expression of large numbers of high-affinity receptors for IL-2 allows these cells to sequester preferentially IL-2 and deprive other T cells of this critical growth factor [41–43]. Other cellular interactions, including alteration of APC function and direct cytotoxicity, have also been proposed as important mechanisms for Treg-cell function [11,31,42,44,45]. A critical question when extrapolating these findings to the clinic is how relevant these studies are for human Treg-cell function. It is very difficult to study the role of specific molecules in Treg-cell function in humans apart from in vitro studies assessing whether a particular interaction is critical for maintenance of the ability of Treg cells to suppress the MLR or xenogenic GVHD in immune-suppressed animal model systems. Determining whether modulation of these structures occurs during the isolation process and/or ex vivo expansion utilized in the clinical protocol is of clear importance. These studies require further investigation to elucidate better the critical requirement of different cell-surface molecules in Treg-cell function in the clinic.

Treg-cell homeostasis in vivo

Like conventional T cells, Treg cells are derived from lymphoid precursor cells that mature in the thymus and are subject to negative and positive selection. This results in mature CD4 Treg cells that have a highly diverse αβ T-cell receptor repertoire that is exported to the peripheral blood and circulate to secondary lymphoid organs and peripheral tissues [46]. In healthy individuals, Treg cells represent approximately 1.5–10% of the CD4 T-cell pool and human peripheral blood contains approximately 10–80 CD4 Treg cells/μL. Like other T-cell populations, peripheral Treg cells are maintained at constant levels through continuous production of naïve Treg cells in the thymus. Mature Treg cells also undergo homeostatic proliferation and both thymic production and homeostatic proliferation are counterbalanced by apoptotic cell death to maintain normal levels of peripheral Treg cells. Although all T-cell populations are subject to homeostatic control, recent studies have demonstrated that distinct control mechanisms are utilized for different T-cell populations. This is particularly evident for Treg cells, where this T-cell subset is uniquely dependent on IL-2 and constitutively proliferates at a higher rate that Tcon cells [47–49]. This high level of proliferation is counterbalanced by increased susceptibility to apoptosis, mediated in part through increased expression of CD95 [47]. As a consequence of this high level of endogenous proliferation, Treg cells have significantly shortened telomeres compared with Tcon cells, and this further promotes cell senescence and increased susceptibility to apoptosis [48].

In the setting of allogeneic HCT, thymic function is markedly impaired, especially in adults, and thymic generation of naïve Treg cells is significantly reduced [47]. Maintenance of normal Treg cell numbers after HCT therefore relies primarily on proliferation of memory Treg cells, which is significantly increased. However, highly proliferative Treg cells have also been shown to have markedly shortened telomeres and express higher levels of CD95 and lower levels of Bcl-2 protein compared with Tcon cells. After allogeneic HCT, Treg cells are therefore more susceptible to apoptosis than Tcon cells, and this homeostatic imbalance contributes to a relative deficiency of Treg cells. This is most evident in patients with chronic GVHD and likely contributes to the persistence of chronic tissue damage in these patients [47].

Clinical translation of Treg-cell biology

The findings that Treg cells suppress GVHD yet allow for GVT responses and more effective immune reconstitution have made the clinical translation of this cell population of high importance. Further, many animal models of autoimmunity have been described where Treg cells have been shown to have immunologic consequences, and therefore the results of clinical translation in the HCT field have enormous implications for other clinical settings [50]. However, there are major limitations in the translation of these concepts to the clinic, including the relatively small numbers of cells that circulate in peripheral blood and the difficulty in isolating this cell population with a rather common phenotype. Although CD4 and CD8 T cells do not constitutively express CD25, human effector T cells express CD25 after antigen activation, in vitro and in vivo. Hence isolation and expansion of $CD4^+CD25^+$ cells often includes activated T cells in addition to Treg cells. Since FoxP3 is an intracellular transcription factor, FoxP3 expression cannot be used for isolation of cells; however, expression of this transcription factor can define the purity of the cell population following separation. Therefore, the search for other markers that could be clinically useful has been of high importance and many studies have revealed a number of potential markers, with lack of expression of CD127 (IL-7 receptor) emerging as the most useful other cell-surface marker identified to date [51,52]. These studies demonstrated that the cell-surface phenotype of $CD3^+CD4^+CD25^+CD127^{low}$ in human

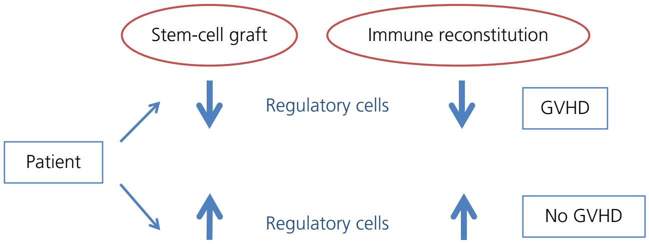

Figure 14.1 The role of regulatory cells in the development of graft-versus-host disease.

samples reliably distinguishes these cells from conventional CD4 T cells ($CD3^+CD4^+CD25^-CD127^{high}$) and CD8 T cells. Isolation of Treg cells based on these markers results in a relatively pure population of polyclonal Treg cells with relatively low contamination by effector T cells.

Role of Treg cells in human GVHD

The role of Treg cells in human GVHD pathophysiology has been assessed in a number of different ways (Figure 14.1). Several studies have attempted to correlate the subsequent clinical development and severity of acute or chronic GVHD with the number of Treg cells in the stem-cell graft. Although not all results in clinical reports have been consistent, most studies have found that increased numbers or increased frequency of Treg cells in the stem-cell products correlated with reduced incidence of GVHD after engraftment [53–55].

Several studies also quantified Treg cells in peripheral blood at various times after transplant and correlated these results with the presence or absence of GVHD. Although the results of these studies have also not been entirely consistent, they generally support the concept that lower numbers of Treg cells are associated with greater risk of acute and chronic GVHD [47,56–65]. Differences in the methods used to detect and quantify Treg cells may help explain some of these discrepancies, but it is also likely that many factors, unrelated to GVHD, influence the number of Treg cells circulating in the blood at various times after transplant. In one study, the relative number of Treg cells early in the post-transplant period correlated with GVHD risk, where patients with fewer Treg cells had higher risk [66]. In a separate study, effective treatment of chronic GVHD resulted in improvement in the number of Treg cells, further supporting the concept that Treg cells are of central importance in the biology of human GVHD [57]. All of these studies have a number of caveats, including the facts that the range of Treg cells in the donor inoculum is relatively narrow and that sampling is usually performed in the blood rather than nodal or GVHD target tissues owing to the difficulty of accessing the latter tissues. Some studies have been able to assess the tissue content of Treg cells at sites of GVHD, further supporting the concept that Treg cells are important in the underlying biology of alloreactivity after stem-cell transplantation [56,67]. Nonetheless, these studies are correlations and do not conclusively define a role for Treg cells in GVHD pathophysiology. Therefore, clinical studies assessing the effects of adoptive transfer of purified populations of cells were eagerly awaited.

Adoptive transfer of Treg cells in allogeneic HCT

Two clinical studies have been published that demonstrate that Treg cells play a major role in controlling GVHD. The first study, at the University of Perugia, was carried out in patients with high-risk leukemia who did not have HLA-matched related or unrelated donors [68]. Patients received ablative conditioning followed by selected $CD34^+$ hematopoietic stem cells from haploidentical donors. Four days prior to stem-cell transplantation, patients received a single dose of highly purified donor Treg cells. Following stem-cell infusion, patients also received a defined dose of conventional donor T cells. Previous studies from this group had demonstrated that haploidentical transplantation is possible without any immunosuppression and with minimal risk of GVHD [69]. However, these patients suffered from very slow immunologic recovery, relapse, and opportunistic infections. The addition of conventional T cells could reduce the risk of infection and perhaps improve GVT reactions, but infusion of donor T cells has been limited by GVHD risk. Specifically, it was found that infusion of as few as 5×10^4 $CD3^+$ donor T cells/kg can result in severe and often lethal GVHD.

A subsequent Perugia study employed a two-step isolation process to purify Treg cells from the haploidentical donor prior to hematopoietic stem-cell mobilization [68]. Briefly, the donor apheresis product was first depleted of CD19 B cells and CD8 T cells and subsequently $CD25^+$ cell selection was used to isolate a population of Treg cells with ~50–75% $FoxP3^+$ expression. All manipulations utilized the CliniMACS separation system (Miltenyi Biotec) and clinical-grade reagents. The infusion of donor Treg cells prior to donor Tcon cells in these studies was based on the hypothesis that the addition of Treg cells prior to the addition of Tcon cells would make it possible to increase the number of Tcon cells that could be safely infused. In these studies, up to $2–4 \times 10^6$ Treg cells/kg were infused without significant clinical toxicity. An equal number of Tcon cells were infused with limited risk of acute GVHD, clearly demonstrating the ability of the Treg-cell population to suppress alloreactivity in vivo. In this first trial, 28 patients were treated and 26 engrafted. Of these 26 evaluable patients, only two developed grade II–IV GVHD [68]. Importantly, patients who received donor Treg and Tcon cells appeared to have improved immune recovery and low risk of disease recurrence. However, transplant-related mortality was still significant, mainly due to infection. Therefore, further improvements are necessary to improve these clinical results. Nevertheless, this study provides clear evidence that Treg cells have potent biological function in vivo in that relatively few of these patients developed significant GVHD despite the infusion of an otherwise unacceptable dose of Tcon cells.

The second study, from the University of Minnesota, used expanded Treg cells from umbilical cord blood (UCB) in an effort to reduce GVHD risk in the double cord blood transplant setting. Given the relatively small number of hematopoietic stem cells in UCB products, two UCB products were used, primarily in adult patients, to enhance engraftment [70]. The use of two UCB donors increases the risk of GVHD, and the Minnesota group performed a clinical trial to examine whether the infusion of third-party ex vivo expanded Treg cells could reduce that risk [71]. In this study, Treg cells were purified from a third partially HLA-mismatched cord blood product using the CliniMACS system to isolate $CD25^+$ cells. Isolated cells were expanded after stimulation with anti-CD3/anti-CD28 Dynabeads and IL-2 for at least 14 days. In most cases, in vitro expansion was extended to provide cells for a second Treg-cell infusion. Seventeen of 23 (74%) patients received the Treg-cell infusion at the target cell dose level. Only five patients received a Treg-cell dose less than the prescribed cell dose because of insufficient culture expansion. Of the 18 patients scheduled to receive two doses, 13 received the targeted Treg-cell dose on days +1 and +15. Overall, 18 patients received a total Treg-cell dose $>30 \times 10^5$ cells/kg. With these results, this study demonstrated that Treg cells could

be expanded from UCB on a clinical scale and there were no infusional toxicities in the 23 patients treated. After infusion, UCB Treg cells could be detected for 14 days, with the greatest proportion of circulating $CD4^+CD127^-FoxP3^+$ cells observed on day +2. Because these are third-party Treg cells, it was not expected that these cells would persist indefinitely. Although it was difficult to assess the biological function of the Treg cells in this study, it could be shown that there was an apparent reduction in GVHD risk compared with a historical control group [71].

Taken together, these two studies provide firm evidence that utilization of Treg cells on a clinical scale is feasible, infusion of the cells does not result in toxicity, and there is evidence for biological activity (Figure 14.2). These studies set the stage for further clinical applications of Treg cells in a variety of clinical settings using highly purified nTreg cells, ex vivo expanded Treg cells, and perhaps induced Treg cells to prevent and treat GVHD. Clearly, several major issues remain to be resolved in future studies. These include the required purity of infused Treg cells, activation status, cell-surface expression of important homing and functional receptors, cell dose, and ability to home to appropriate biological sites. Whether multiple infusions of Treg cells are required to maintain functional suppression of GVHD and establish long-term tolerance towards recipient tissues remains to be elucidated. Finally, whether enhancement of Treg-cell function may also suppress GVT responses must also be carefully evaluated in future studies. Nonetheless, these studies provide firm evidence that clinical translation is possible and future studies will delineate the potential clinical utility of this important population of regulatory cells.

Impact of immunosuppressive medications on Treg-cell function

A number of studies have explored the impact of conventional immunosuppressive medications on Treg-cell function. These studies revealed that calcineurin inhibitors such as cyclosporine A and tacrolimus generally inhibit Treg-cell function, but this can be partially overcome by administration of IL-2 [72,73]. Both of these immunosuppressive medications suppress IL-2 production by T cells, and therefore the reduction in production of this cytokine that Treg cells require yet do not produce is thought to be an additional mechanism by which these agents suppress Treg cells in vivo. Other immunosuppressive medications, such as rapamycin (sirolimus), appear to be more permissive for Treg-cell function [74]. This can be explained by the observation that upon T-cell receptor activation, conventional $CD4^+$ T cells signal primarily though the mammalian target of rapamycin (MTOR) pathway, whereas CD4 Treg cells mainly utilize the Stat5 pathway [73]. In more recent studies, novel agents have also been examined for their effect on Treg-cell function. For example, hypomethylating agents, such as decitabine and azacitidine, induce FoxP3 expression in Treg cells and suppress GVHD in vivo in animal models [75]. The JAK/STAT pathway also plays a role in proliferation of activated Tcon and Treg cells and methods are being developed to suppress selectively Tcon cells through modulating this pathway [32,76]. α_1-Antitrypsin is another novel agent that has been found to reduce GVHD by suppressing pro-inflammatory cytokines, selectively reduce expansion of effector T cells, and enhance recovery of Treg cells [77,78]. Thus far, most of these studies have been performed in vitro or in animal models, and to date there is no accepted immunosuppressive medication strategy avoiding calcineurin inhibitors in clinical HCT. The combination of rapamycin and mycophenolate mofetil (MMF) has been utilized clinically and resulted in higher numbers of Treg. However, this regimen was associated with excessive toxicity and no clear reduction in GVHD risk compared with historical experience with more conventional calcineurin inhibitor (CNI)-based combinations [79].

Activation and expansion of Treg cells in vivo

Although adoptive transfer experiments are clearly an effective clinical approach to modulate Treg-cell function after HCT, alternative strategies have been explored to expand Treg-cell populations in vivo. In animal models, this can be accomplished through administration of IL-2, a critical homeostatic cytokine that Treg cells require but do not produce [3,80]. In these studies, treatment with IL-2 resulted in selective expansion of Treg cells in several different animal models and in humans [81–84]. When tested in models of autoimmunity, selective expansion of Treg cells in vivo following IL-2 therapy effectively reversed disease manifestations [82]. In models of allograft rejection, IL-2 therapy promoted long-term acceptance of allografts without additional immune suppression [81]. In models of allogeneic HCT, IL-2 has been combined with rapamycin (sirolimus) to enhance suppression of conventional CD4 T cells. In this model, the combination of IL-2 plus rapamycin improved survival and reduced GVHD lethality. This was associated with selective expansion of natural Treg cells and also conversion of induced Treg cells from conventional donor CD4 T cells and reduced production of inflammatory cytokines [85].

The use of low-dose IL-2 to expand Treg cells has been explored by investigators at the Dana-Farber Cancer Institute in patients with refractory chronic GVHD [86]. Their earlier studies demonstrated that patients with chronic GVHD have low numbers of Treg cells and the administration of low-dose IL-2 by subcutaneous daily injection results in the expansion of Treg cells. Since all Treg cells constitutively express high-affinity IL-2 receptors, low concentrations of ligand are sufficient to initiate receptor-mediated signals. The studies therefore examined relatively low doses of IL-2 compared with doses commonly used for the treatment of metastatic melanoma. Three dose levels were tested and 29 patients with long-standing chronic GVHD were enrolled in the study. It was found that 1×10^6 units/m^2 was a tolerable dose of IL-2 that could be given as a daily injection over an 8-week course of therapy. Importantly, this treatment was associated with an eightfold increase in Treg cells in the peripheral blood without any increase in conventional CD4 or CD8 T cells. NK cells were also affected and increased 2.5-fold during IL-2 therapy. Of the 23 evaluable patients, 12 had major responses involving several different clinical sites of disease. In patients who had clinical responses, daily IL-2 therapy was resumed after a 4-week rest period and continued for over 1 year in several patients. Although IL-2 can also promote the expansion of effector T cells, the effect of IL-2 on Treg cells predominated and none of the patients in this trial experienced worsening of chronic GVHD while on low-dose IL-2 therapy.

In the context of this clinical trial, further studies were carried out to determine the biologic effects of IL-2 therapy [87]. Prior to starting IL-2, all patients had reduced numbers of Treg cells in peripheral blood. During the 8-week treatment period, IL-2 induced a series of sequential changes in Treg-cell homeostasis in all patients, including increased proliferation and increased thymic export of naïve Treg cells. Intracellular expression of Bcl-2 was also increased and expanded Treg cells became more resistant to apoptosis in vitro. Low-dose IL-2 had minimal effects on Tcon cells and this resulted in a fivefold increase in the Treg/Tcon cell ratio. Taken together, these findings define the mechanisms whereby low-dose IL-2 therapy restores homeostasis of CD4 T cell subsets and promotes the re-establishment of immune tolerance in patients with active chronic GVHD. These studies indicate enormous potential for expansion of Treg cells, and future studies combining adoptive transfer of Treg cells with low-dose IL-2 therapy may further enhance the potential clinical benefit of this approach [88]. Preclinical animal models have helped set the stage for various approaches focused on the modulation of CD4 Treg cells after allogeneic HCT, with additional clinical trials being organized in several different clinical settings.

Natural killer T cells

In addition to Treg cells, other cell populations have been shown to have immune modulation activity. A rare population of NK cells that co-express T-cell markers (NKT cells) have also been shown to be biologically important and have potent immunomodulatory activities primarily through the production of immune-regulating cytokines such as IL-4 [89,90]. NKT cell populations have been shown to suppress different auto- and alloimmune functions in animal modeling studies, again setting the stage for clinical translation. Invariant NKT (iNKT) cells are selectively activated by glycolipid antigens expressed by CD1d molecules. These cells express a distinct T-cell receptor (TCR) characterized by an invariant TCRα chain coupled with a variable TCRβ chain. Two major populations of iNKT cells have been described that have distinct functional activities and produce different sets of cytokines after activation [89,91]. These cells appear to play an important role in regulating immune responses after HCT [92,93]. Similarly to the studies with Treg cells, correlations have been made between the iNKT cell content of the stem-cell graft and subsequent GVHD risk [94]. In these studies, increased numbers of iNKT cells in the stem-cell graft were associated with reduced incidence of GVHD after transplant. Similarly, analysis of iNKT cell reconstitution after transplant demonstrated that early recovery of iNKT cells was predictive of a lower risk of GVHD and improved survival [95].

One approach to the translation of these concepts came from the studies of Strober and co-workers, where the use of total lymphoid irradiation (TLI) in combination with antithymocyte globulin (ATG) in murine models resulted in alteration of the ratio of conventional CD4/CD8 T cells to NKT cells and a marked reduction in GVHD risk [96]. In this model, NKT cells were shown to be relatively radioresistant such that there was less suppression following exposure to TLI altering the ratio dramatically in the tissues of the animals prepared with TLI–ATG. As a result, TLI–ATG-prepared animals could be transplanted with 1000 times the number of conventional CD4/CD8 T cells compared with TBI-conditioned animals that would otherwise cause lethal GVHD. IL-4 production was critically important, as was activation with CD1, as knockout strains of animals deficient in either IL-4 or CD1 had no such biological effect. Therefore, these studies demonstrated that altering the host conditioning could impact the ratio of NKT-cell regulatory cell populations and have profound biological effects after HCT. Further, it was demonstrated that interaction of the NKT cells with Treg cells in the donor graft was critically important for biological function in these animal models [97].

These preclinical studies set the stage for clinical translation with the TLI–ATG regimen, which was found to be tolerable on an outpatient basis and resulted in marked reductions in acute GVHD and also transplant-related mortality [98–100]. Further, in patients transplanted with TLI–ATG, it was found that there was a rise in recipient NKT cells immediately after conditioning and prior to the infusion of the donor inoculum, correlating with the animal model predictions [98]. TLI–ATG conditioning was found to be well tolerated and applicable to the treatment of older patients and patients with comorbid medical conditions, including those who had received prior autologous transplants [99]. Further, the reduction in GVHD risk allowed for the exploration of combined bone marrow and solid organ grafts for tolerance induction, initially in the setting of kidney transplants where a number of patients have been successfully tapered off all immunosuppressive medications [101] (see Chapter 12).

Adoptive transfer of NKT cells has also been explored, where it was found that these cell populations are also capable of suppressing GVHD [102,103]. Interestingly, even lower numbers of cells compared with Treg cells are functional in similar animal models [104]. Whereas Treg cells have been clearly shown to suppress the proliferation of alloreactive conventional T cells in models using bioluminescent imaging, it was demonstrated that following the infusion of NKT cells, there is no such suppression of conventional T-cell proliferation, suggesting that NKT cells function through a different mechanism of action. In addition, the use of αGalCer has been shown to activate NKT cells that also interact with Treg cells, resulting in suppression of GVHD in animal models [105]. This concept has been translated to the clinic in a phase I/II clinical trial that is ongoing. The concepts developed in animal modeling have been shown to have important biological consequences in suppressing GVHD reactions, reducing transplant-related morbidity and mortality with appropriate extension to the clinic.

Mesenchymal stromal cells

Mesenchymal stromal cells (MSCs) are a heterogeneous population of adherent cells isolated from bone marrow, adipose tissues, and other sites, which have been studied in a number of different clinical venues [106]. MSCs have been shown to have immunomodulatory and anti-inflammatory properties and have been evaluated in the treatment of both acute and chronic GVHD. Results in animal studies have demonstrated that MSCs suppress alloreactive T-cell proliferation, but results have been mixed with respect to the ability of MSCs to suppress GVHD [107,108]. In other studies, repeated injections of MSCs delayed but did not prevent GVHD [109]. Similar results were observed in a canine model of GVHD where MSCs, despite having properties similar to those of human MSCs, failed to improve the survival of dogs undergoing allogeneic HCT [110]. Despite these somewhat discouraging results in animal model systems, there have been case reports of patients with severe refractory GVHD who have responded to MSC infusions [111]. These responses prompted more extensive testing, including prospective phase II trials in patients with acute GVHD in addition to corticosteroids as front-line therapy. In one study, 32 patients received one of two doses of MSCs (2×10^6 vs. 8×10^6 MSCs/kg) within 48 hours of the first treatment with corticosteroids. A high response rate of 94% was observed independent of the dose of MSCs administered [112]. On the basis of these promising results, two prospective randomized trials were conducted comparing MSCs with placebo. Although final results are pending, they were reported not to reach their primary end-points of improvement of GVHD response rates, although a subset analysis of patients with liver GVHD may have responded favorably to MSC treatment.

Despite these setbacks, there continues to be significant interest in MSCs for the treatment of acute and chronic GVHD [113]. Overall, evaluation of the potential therapeutic role of MSC has been limited by the heterogeneity of the MSC populations that have been administered and the undefined mechanisms of action of these cells in vivo. Critical factors that contribute to the heterogeneity of MSCs include whether the cells used in clinical trials are autologous or allogeneic, what tissue they were derived from, the method of isolation, the number of in vitro cell divisions, and the cell surface phenotype after expansion [114]. Further studies are needed to address these issues and establish in vitro potency assays for the manufactured MSC product that can be used to compare different MSC products and predict the functional activity of these cells in vivo.

Myeloid-derived suppressor cells

Myeloid-derived suppressor cells (MDSCs) have been identified as cells that accumulate in tumor tissues and inhibit immune responses [115]. MDSCs can be cultured from bone marrow cells in the presence of granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF) and have been found to inhibit in vitro immune responses. These cells have also been studied in murine models of allogeneic HCT where addition of MDSCs to stem-cell grafts suppressed GVHD and elimination of MDSCs from grafts exacerbated GVHD after transplant [116]. Following transplant, increased numbers of MDSCs were found in mice without GVHD; accumulation of MDSCs was also noted at sites of tumor relapse. However, a subset of MDSCs responsive to IL-13 has been reported to suppress GVHD without inhibiting GVT reactions [117].

Other regulatory populations

Other populations of regulatory cells, including CD8 Treg cells and regulatory B cells, have also been demonstrated to have immune regulatory functions in animal models [118–120]. CD8 Treg cells that are induced from conventional CD8 T cells have been found to suppress GVHD potently [121,122]. However, the potential clinical use of these cells is challenged by the relative paucity of these cells in peripheral blood, the variable phenotypes that have been described, and whether such populations can be induced in vitro. Although most studies have been carried out in murine models, populations of CD8 Treg cells have been described in humans [123,124]. However, it is not known whether CD8 Treg-cell populations in humans are the same as those found in murine systems, and the mechanisms by which these cells regulate other immune cells have not been well characterized. Importantly, the potential role of CD8 Treg cells in GVHD after allogeneic HCT in humans has not yet been studied.

Conclusion

Immune regulatory mechanisms play a central role in a variety of different disease settings. In acute and chronic GVHD, dysfunctional immune reactions that are improperly regulated characterize the pathophysiology of these diseases. The development of strategies to enhance immune regulatory cell number and function and also the adoptive transfer of regulatory cell populations hold significant promise for improving outcomes for patients undergoing allogeneic HCT. Clearly, many issues remain to be elucidated and technical improvements are required. However, results from the early clinical studies adapted from animal modeling have demonstrated the biological impact of these cell populations and the feasibility of clinical translation. These studies have important implications in the field of HCT but also are relevant to other clinical conditions, such as autoimmune diseases, and the induction of solid organ transplantation tolerance.

Introduction

Hematopoietic cell transplantation (HCT) is complicated by post-transplant immune deficiency, which is more profound after allogeneic than autologous HCT. Cytoreductive conditioning regimens eliminate tumor cells and significantly deplete the recipient's immune system, in particular cells of the lymphoid lineage (expertly reviewed in [1]), and allow for successful engraftment of hematopoietic stem cells (HSCs) in their bone marrow niche. Although this depletion of the adaptive immune system promotes HCT engraftment as it prevents host cells from attacking donor stem cells, delayed lymphoid recovery following immune depletion is associated with a high degree of morbidity and mortality, and can potentially also lead to malignant relapse [2,3]. Post-transplant immune depletion is particularly striking within the T cell compartment, which is extremely sensitive to negative regulation and remains depressed for a considerable time (Figure 15.1). Consequently, regeneration of the immune system remains a significant unmet clinical need. There are currently no US Food and Drug Administration (FDA)-approved strategies for immune reconstitution. However, several preclinical and clinical studies have identified promising therapeutic strategies for immune regeneration.

In this chapter, we review immune reconstitution following HCT, with a particular emphasis on factors that contribute to delayed immune recovery post-transplant and the clinical consequences. We also discuss current clinical and research assays to monitor post-HCT immune recovery and highlight some of the potential strategies that are currently under investigation to enhance immune recovery in HCT recipients.

Steady-state lymphopoiesis

HSCs are central throughout life for their ability to differentiate into and develop all hematopoietic lineages [4]. Branching towards myeloid and lymphoid lineages occurs at the level of hematopoietic stem and progenitor cells [5]. In fact, early hematopoietic progenitors have been phenotypically identified that are either fully committed or biased towards the lymphoid linage [6–8]. Furthermore, there is increasing evidence in animal studies that functional branching occurs at the most primitive HSCs, with both lymphoid- and myeloid-biased stem cells described [9,10]. Changes in the ratio between myeloid- and lymphoid-biased stem cells may explain the age-associated decline in lymphoid function [11,12]. Differentiation of lymphoid progenitors down the B lineage in the bone marrow (BM) or T lineage in the thymus is a complex process involving the transcriptional commitment of multipotent progenitors, egress from the BM, and entry to the thymus – in the case of T cells – and progression through a series of distinct developmental stages that are tightly controlled by their respective microenvironmental niches. This process, which is continuous for the duration of life, albeit declining significantly with age, results in the formation of mature naïve T and B cells that form the pillars of the adaptive immune system.

Progression from HSC to B cell occurs through a series of distinct developmental steps and relies on the production of specific factors by the BM niche along with downstream signaling events that promote the differentiation and development of mature B lymphocytes [13]. T-cell development is more complicated as it begins in the BM and continues through series of well-defined stages in the thymus. The thymus has traditionally been thought to contain no self-renewing cells capable of maintaining thymopoiesis [14], instead relying on the importation of progenitors that periodically egress the BM to enter the circulation and seed the thymus (comprehensively reviewed in [15,16]), although two recent studies in mouse models suggest that there are some self-renewing T-lineage progenitors resident in thymus that contribute towards thymopoiesis, at least in the setting of immune deficiency [17,18]. Although the underlying process of thymus seeding from circulating progenitors is well established, the precise identity of the circulating T-cell progenitor has remained elusive. However, it is becoming increasingly clear that there are multiple circulating cells with the capacity for T-cell differentiation that can seed the thymus, differing in their phenotype and in their lineage restriction [15,16]. Moreover, the precise mechanisms of their entry into the thymus are only just beginning to be understood (reviewed in [16]). Once in the thymus, T-lineage progenitors undergo a series of maturation and developmental steps, in addition to positive and negative selection depending on their specific T-cell receptor and its affinity for self or foreign antigen, in highly specialized microenvironmental zones that result in the formation of naïve T cells ready for export to the periphery (reviewed in [19]). Although T-cell development is predominantly restricted to the thymus, recent studies have found that there could

be some degree of extrathymic T-cell development, including conventional T-cell development in the human tonsil [20–22]. This is particularly interesting in light of another study suggesting that naïve T-cell output becomes negligible in human thymus with age [23]. However, despite its apparent redundancy in aged humans in the steady-state, it is likely that the thymus is of considerable benefit for reconstitution of the naïve T-cell receptor repertoire after immune depletion.

What are the causes of post-transplant immune deficiencies?

There are several factors that can influence the extent and duration of immune deficiency after HCT, including age-associated thymic involution, thymic damage due to pretransplant chemotherapy, radiation and/or antibody therapy, the source and purity of the cells transplanted, disparity of MHC and minor histocompatibility antigen (mHA) between donor and host, the use of post-transplant immune suppression, and graft-versus-host disease (GVHD).

Relationship between recipient conditioning and immune reconstitution

Successful HSC engraftment requires conditioning to (1) create space in the BM for effective engraftment of donor HSCs and (2) eliminate host-versus-graft rejection by recipient immune cells. Typically, conditioning includes cytoreductive chemotherapeutic drugs such as cyclophosphamide and busulfan, total body irradiation, and/or antibodies [such as antithymocyte globulin (ATG) or alemtuzumab] [24]. This results in severe depletion of all hematopoietic cells of the immune system. Both alkylating chemotherapeutics and irradiation target highly proliferative cells [25], including developing and naïve lymphocytes, making them particularly depleted following treatment [26]. The use of ATG (or alemtuzumab) further depletes host T cells and could impair the early development of donor-derived T cells due to the persistence of these antibodies in the patient for several weeks after administration.

Increasing the severity of conditioning can considerably increase the engraftment of unrelated unmatched HSCs, but can also increase treatment-associated toxicity and further prolong post-transplant immune deficiency [27]. Moreover, hematopoietic niches in both the BM and thymus can be significantly impacted by HCT conditioning. In the thymus, in particular, there can be significant damage to the epithelial microenvironment, leading to reduced T-cell development. The severity of thymic damage due to the conditioning regimen is dose related, affects in particular the epithelial microenvironment, and is associated with the pace of post-transplant immune recovery [28–32]. Although the epithelial compartment in the thymus of young patients can recover from these cytoreductive treatments [33,34], this regenerative ability is age dependent and older patients are less capable of thymic regeneration [35]. The thymus is also extremely sensitive to immunosuppressive strategies used as GVHD prophylaxis, and also the damage caused by GVHD itself and its treatment (such as high-dose corticosteroids) [36–40].

Relationship between graft composition and immune reconstitution

The most effective way to reduce the incidence of GVHD in HLA-unmatched or minor-mismatch HCT is to remove specifically all donor T cells from the graft, or create an inoculum with purified HSCs. Despite considerably reducing the risk of GVHD, patients receiving grafts that have been depleted of donor T cells or enriched for HSCs are also likely to undergo prolonged immune depletion [41,42] and increased morbidity and mortality from infection [43]. Moreover, in the case of patients receiving HCT for hematologic malignancies, the removal of antileukemic donor T cells diminishes the likelihood of a beneficial graft-versus-leukemia effect. Therefore, in these cases, the use of purified grafts can potentially lead to an increased incidence of malignant relapse [44,45].

It should be noted, however, that there are significant differences in the potency of graft-versus-leukemia effects based on the malignant disease being treated. For example, in patients with chronic myelogenous leukemia (CML), T-cell depletion (TCD) is associated with an increased risk of relapse [46], whereas donor lymphocyte infusion (DLI) leads to a majority of patients in the TCD group achieving complete remission and no difference in overall survival, compared with recipients of non-TCD grafts. In contrast, studies in patients with acute myeloid leukemia (AML) or acute lymphoblastic leukemia (ALL) have reported comparable low rates of relapse after TCD HCT [47–49]. A recently published retrospective analysis in AML that compared 115 patients who received TCD grafts after ablative conditioning with a cohort of 181 patients who received unmodified grafts demonstrated no significant differences in the rate of relapse at 3 years between TCD and unmodified graft recipients (18% vs. 25%, $p = 0.3$) [50].

One of the most critical determinants for successful HCT is the number and quality of HSCs transplanted [51]. Although progressive deterioration of the immune system with age is a widely studied phenomenon [52,53], at least part of this degeneration can potentially be attributed to the decreased function of HSCs (reviewed in [11]). With age, HSCs exhibit a reduced engraftment and reconstitution potential [54,55], and an overall skewing away from lymphoid and towards myeloid lineages [56,57]. As a result, the age of an HSC donor can be of considerable clinical importance in determining HCT outcomes [58,59].

In addition, the source of HSCs can also have a significant impact on HCT outcomes. At present, commonly used HSC sources are BM, peripheral blood (PB), and umbilical cord blood (UCB). Homing to the BM of BM-derived HSCs is more efficient than PB-derived HSCs [60]; however, hematopoietic engraftment, as measured by platelet and neutrophil reconstitution, is significantly faster using PB [61]. This can be attributed to the fact that recipients of PB transplant receive fewer long-term HSCs and more committed multipotent progenitors (MPPs) than from adult BM [61]. Although initial studies seemed to indicate delayed immune reconstitution after HCT using UCB, postulated to have been due to the composition of UCB as comprising only primitive HSCs compared with BM or PB [62,63], later studies suggested that the use of ATG during conditioning might have been the reason for this delay [64].

Impact of GVHD on immune regeneration after HCT

Although ideally all HCT patients would receive an infusion of HLA-matched cells, giving the best chance of a successful outcome [24,65], this is not always possible. In fact, it is estimated that HLA-matched related HCT is performed in only approximately 40% of cases [66]. Several studies have identified that hematopoietic organs can be direct targets of alloreactive T cells during GVHD. Specifically, the thymus and BM microenvironmental niches, which are critical for supporting hematopoiesis in the BM and thymopoiesis in the thymus, are severely impacted during GVHD [38–40,67]. This leads to severe and prolonged immune depletion and can explain the widely reported pan-cytopenia observed in patients with GVHD.

Consequences of prolonged immune depletion

The rate and quality of hematopoietic engraftment and immune reconstitution have a significant impact on morbidity and mortality in HCT. This is particularly the case after allogeneic HCT. Deficiencies in B- and T-cell reconstitution after allogeneic HCT can persist for over 1 year, and are associated with an increased risk of infections [68–70], decreased responses to vaccines [71], recurrence of primary malignancy [72,73], and the development of secondary malignancies [44]. Despite novel regimens to prevent and treat invasive viral, fungal, and parasitic infections, opportunistic infections represent an important primary cause of post-transplant morbidity and mortality [68,74]. Not only is the overall risk of infection greater following unrelated HCT, it also extends further post transplant, due to delayed immunologic recovery [68,74].

Endogenous immune reconstitution after HCT

Reconstitution of innate immunity

Innate immunity is comprised of two fundamental components: (1) hematopoietic cells including neutrophils, macrophages, and natural killer (NK) cells and (2) the non-hematopoietic compartment, which includes physical barriers such as skin and mucosal surfaces [75,76]. Although the non-hematopoietic components can be impacted by HCT conditioning including chemo- and radiation therapy, they are rapidly restored following HCT [77]. However, in cases of GVHD, physical barriers, including skin and mucosa, are specifically targeted [78]. The first cells to engraft following HCT are monocytes followed by granulocytes, platelets, and NK cells [77]. Neutrophil counts return to normal within 2–4 weeks; however, functionally they may remain suboptimal for a short time after transplant [79]. Although macrophages are not significantly depleted as a result of transplant conditioning, they are gradually replaced by donor-derived macrophages over the first several months after HCT [80]. Functionally, monocytes may remain suboptimal for up to 1 year [81,82]. NK cells recover both numerically and functionally within the first few weeks following HCT [83]. The importance of NK cell recovery on engraftment and relapse is discussed elsewhere (Chapter 15).

Reconstitution of adaptive immunity

Despite being exquisitely sensitive to negative stimuli, lymphopoiesis has a remarkable ability for endogenous regeneration, allowing for renewal of immune competence after infection, shock, or cytoreductive therapies [36,84]. However, recovery of the adaptive immune system, and in particular T cells, is slow, reflected by prolonged depletion of naïve T cells and reduced function [85,86]. Recovery of T-cell numbers can occur via (1) peripheral expansion of (memory) T cells or (2) endogenous T-cell development. Although there is peripheral expansion of T cells in HCT recipients of a non-T-cell-depleted graft, this ultimately leads to a narrowing of the T-cell receptor repertoire and impaired adaptive immunity [26,33]. In fact, $CD8^+$ T cells recover rapidly in both young and aged patients [87]; however, these primarily expand to fill the niche by clonal expansion [88,89].

Therefore, effective reconstitution of T-cell receptor repertoire diversity and capacity requires a functional thymus [90]. This thymic dependence in generating an effective T-cell repertoire after HCT is a critical hurdle in elderly patients, where thymic atrophy is a natural occurrence of aging [91]. Although recent studies suggest that the aged human thymus does not contribute any naïve T-cell production in the steady state [23], the reported presence of T-cell receptor excision circles (TRECs) and other markers of recent thymic emigrants suggests that, after transplant, the thymus can indeed contribute towards the T-cell pool [41,92,93]. However, in comparison with children, adults whose thymus has atrophied as a consequence of age are significantly impaired in their ability to recover following chemotherapy or HCT [33,85,94]. Full immune recovery is thought to be possible up until middle age, whereas in older patients the naïve T-cell receptor repertoire is never fully restored [95], and has been linked to infectious morbidity [69]. Although not as significant as the depletion of T cells, there is also considerable delay in reconstitution of B cells [96]. Much like the T-cell receptor repertoire, the B-cell antibody repertoire is also severely diminished and suffers a prolonged recovery [97], lasting on average 6 months after autologous and 9 months after allo-HCT [98]. Following allo-HCT, this diminished B-cell reconstitution is predominantly due to GVHD and its treatment [99].

Functional analysis of T-cell reconstitution (monitoring)

A number of approaches are available to assess post-transplant immune recovery (Table 15.1). These range from relatively simple and readily available clinical parameters such as absolute lymphocyte count (ALC), measure of lymphocyte subsets ($CD4^+$ and $CD8^+$ T cells, NK cells, B cells) or antibody titers, to more complex and less routine assays of T- and B-cell repertoire.

The absolute lymphocyte count has been shown to be predictive of survival and relapse after both autologous and allogeneic HCT. In studies performed at the Mayo Clinic, early lymphocyte recovery, defined as an ALC >500 cells/μL at day 15, was an independent predictor of improved progression-free and overall survival after autologous HCT in patients with multiple myeloma, non-Hodgkin lymphoma (NHL), mantle cell lymphoma, Hodgkin lymphoma, acute myelogenous leukemia, primary systemic amyloidosis, and metastatic breast cancer [100]. The findings of these retrospective

Table 15.1 Tests for analysis of immune reconstitution

Test	Cell population	Clinical vs. investigational	Interpretation
Quantitative tests			
Hematology			
CBC + differential	Neutrophils Lymphocytes	Clinical	Neutrophil recovery Lymphocyte recovery
Flow cytometry			
Lymphocyte subsets	T, B, NK cells	Clinical	Recovery of lymphocyte subsets

studies were further confirmed in a prospective study in patients with NHL that also identified NK cells as the key lymphocyte subset at day 15 affecting survival [101]. In addition, development of lymphopenia measured by ALC post-autologous HCT was associated with a higher risk of relapse of diffuse large B-cell lymphoma (DLBCL) [102]. Similarly, studies performed in patients undergoing allogeneic HCT have also shown an association between ALC and post-transplant outcomes. In recipients of conventional grafts, higher ALC at day 21 or 30 was associated with improved overall and disease-free survival, and also lower relapse rates [45,103].

In patients undergoing partially T-cell-depleted stem-cell transplants with early T-cell add-backs, an ALC at day 30 above the median was associated with improved survival, and a lower incidence of relapse, non-relapse mortality, and acute GVHD [104]. Similar results were observed in patients with CML who underwent the same transplant approach [105]. Furthermore, in CML patients, absolute NK cell numbers at day 30 also predicted survival in addition to the rate of molecular remission. In another study of CD34^{+} selected grafts with limited T-cell add-back, ALC at day 30 was also a strong predictor of non-relapse mortality and overall survival [106]. Finally, in recipients of umbilical cord blood transplant (UCBT), ALC at day 30 also predicted progression-free and overall survival [107].

Quantification of lymphocyte populations, including T, B and NK cells, is also performed on a routine clinical basis. Early CD4^{+} T-cell recovery has been shown to be correlated with overall survival [108], non-relapse mortality [108,109], and the risk of opportunistic infections [108,109]. Progression-free survival also correlated with higher levels of CD3^{+} and CD8^{+} T cells, in addition to regulatory T cells and myeloid dendritic cells, in a prospective study of 95 patients undergoing ablative allogeneic HCT [110].

More recently, multiparameter flow cytometry has been used to define subpopulations of T, B and NK cells further, and also myeloid subsets such as dendritic cells. CD4^{+} and CD8^{+} T-cell subsets include naïve, effector, effector memory, and central memory subpopulations defined by CD45RA, CD28, CD27, CD62L, and CCR7 expression [111–113]. The combination of CD45RA and CCR7 expression distinguishes naïve (CD45RA^{+}CCR7^{+}), central memory (CD45RA^{-}CCR7^{+}), effector memory (CD45RA^{-}CCR7^{-}), and effector (CD45RA^{+}CCR7^{-}) T cells. For example, effector memory CD4^{+} and CD8^{+} T cells were identified as the predominant T-cell subset early after T-cell-depleted allogeneic major HCT [93]. Additional CD4^{+} T-cell subsets include regulatory T cells, defined by co-expression of CD4, high expression of CD25 and FoxP3 [114], and T helper 17 cells that secrete interleukin-17 [115]. In addition, thymic output can be assessed by detection of recent thymic emigrants (RTEs), identified by the CD4^{+}CD45RA^{+}CD31^{+}CD62L$^{\text{bright}}$ CD95$^{\text{dim}}$, and CD8^{+}CD103^{+}CD62L$^{\text{bright}}$CD95$^{\text{dim}}$ phenotypes [116,117]. B cells can also be divided into memory versus naïve B-cell populations by their expression of CD27, IgM, and IgD [118,119]. These markers distinguish between CD27^{-}IgD^{+} naïve B cells, CD27^{+}IgD^{+} "class able to switch" memory cell, and CD27^{+}IgD^{-} "isotype-switched" memory cells [120]. Different NK populations include NK and TCR-Valpha-24^{+} NKT cells. Finally, dendritic cells include myeloid DCs (CD123$^{\text{low/+}}$CD11c^{+}) and plasmacytoid DCs (CD123$^{\text{bright}}$CD11c$^{\text{neg}}$) [121]. Flow cytometry is also used in the identification of antigen-specific responses using either intracellular cytokine detection or tetramers (see below).

In addition to quantitative tests, a number of functional assays provide important information on post-transplant immune recovery. T-cell proliferative responses (measured by ^{3}HTdR incorporation) to mitogens (PHA and OKT3), recall (*Candida*, tetanus), viral [cytomegalovirus (CMV), herpes simplex virus (HSV), varicella zoster virus (VZV), adenovirus], and allogeneic antigens provide an estimate of T-cell function [68,122,123].

More quantitative functional assays include the ELISPOT, intracellular cytokine secretion detected by flow cytometry, and tetramers. The first two provide functional information by detecting antigen-specific cytokine production by CD4^{+} or CD8^{+} T cells. The last assay directly measures T cells that react with particular peptide–MHC complexes, including cells that may have no functional activity. Antigen-specific cytokine secretion can be elicited by stimulation with cells, lysates, proteins, or peptides. In particular, the use of protein-spanning pools of overlapping pentadecapeptides has the advantage of being able to detect both CD4^{+} and CD8^{+} responses and not be limited by the patient's HLA [124]. These assays can be used to detect viral-specific responses including those to CMV [125,126] and Epstein–Barr virus (EBV) [127,128], and also responses to tumor antigens such as WT1 [129,130]. CMV-specific responses may predict patients who are at higher risk of CMV reactivation or recurrent viremia [125,126]. In contrast, the risk of post-transplant lymphoproliferative disorder (PTLD) did not appear to be predicted by the frequency of EBV-specific T lymphocytes [128]. These assays can also be used to track cells after adoptive transfer [131,132]. One of the advantages of flow cytometric intracellular cytokine secretion is the ability to detect polyfunctional T cells that secrete multiple cytokines.

Polyfunctional T cells have been demonstrated in a number of preclinical models of infectious diseases and also in patients infected with HIV-1 or immunized using vaccinia constructs [133,134]. These studies indicate that polyfunctional T-cell responses correlate with improved control of viral replication, suggesting that an effective vaccine should attempt to elicit these types of responses [135]. Tumor-specific polyfunctional CD8$^+$ T cells have also been detected patients with advanced melanoma immunized against gp100 and tyrosinase [136].

In addition to the use of flow cytometry to assess thymic output, quantification of TRECs, measured by real-time quantitative polymerase chain reaction (PCR) in purified CD4$^+$ and CD8$^+$ T cells according to a method developed by Douek et al. [137], can be used as markers of thymopoiesis. TRECs have shown more rapid recovery in younger recipients and in recipients of conventional grafts compared with T-cell-depleted grafts [138], whereas the occurrence of chronic GVHD significantly decreases TRECs [139]. Furthermore, low TREC values correlated strongly with severe opportunistic infections [138,140]. Levels of TRECs have also been compared between recipients of different stem-cell sources (related, unrelated donors, cord blood), and were found to be comparable by 6 months after transplantation [110]. Similarly to TRECs, the detection of kappa-deleting recombination excision circles (KRECs) reflects newly derived functional bone marrow B cells [141,142].

In addition to the quantitative and functional assays described above, a more detailed understanding of the recovery immune system is based on the analysis of T-cell receptor (TCR) and B-cell receptor (BCR) gene rearrangement diversity, which is typically performed using molecular techniques. TCR repertoire diversity within each Vbeta subset is analyzed using the CDR3 size spectratyping method [143,144]. Similarly, the immunoglobulin heavy chain (IGH) diversity is analyzed using Vh primers.

With the advent of next-generation sequencing, an increasingly detailed analysis of T- and B-cell diversity is emerging. Using this type of approach, we recently studied TCR diversity in allogeneic HCT and found significantly higher diversity in CD4$^+$ T cells than CD8$^+$ T cells, highlighting the need to study these populations separately [145]. Furthermore, a comparison of recipients of different types of HCT showed that the most rapid recovery in diversity was seen in cord blood recipients, followed by conventional grafts and T-cell-depleted grafts. After 6 months, cord blood recipients approximated the TCR diversity of healthy controls. This approach also allows the identification and monitoring of individual clonotypes, including known clonotypes specific for viral epitopes.

The study of immune reconstitution after HCT relies on a variety of quantitative and qualitative assays. With the advent of new technology such as deep sequencing and its ability to provide information not only on TCR diversity but also on the frequency of specific clonotypes over time, future prospective studies will need to use an integrated approach where several complementary methods are used simultaneously to analyze immune recovery. It will then be possible to correlate the data obtained using the different methods and also these measures of immune recovery with clinical outcomes such as survival, infections, and relapse [110,146].

Therapeutic strategies to improve immune reconstitution

Several strategies have been developed in preclinical studies that could boost immune reconstitution after HCT, although to date only a few have progressed to clinical trials. These strategies include the exogenous administration of recombinant cytokines or growth factors, hormone-based therapies, and adoptive cell therapy.

Cytokines and growth factors

Several of the current strategies for promoting immune regeneration focus on the use of physiological cytokines and growth factors. Exogenous administration of keratinocyte growth factor (KGF), interleukin (IL)-7, Flt-3 ligand (Flt3L) and growth hormone (GH) has shown promise for their regenerative potential.

One of the most promising immune-boosting therapies, and one with some positive clinical data, is the pro-lymphopoietic cytokine IL-7, which can act directly on T and B lymphoid precursors [147,148]. Treatment with IL-7 enhances thymopoiesis and recent thymic emigrants in addition to aiding peripheral T-cell function in aged mice or following allo-HCT [149,150]. The mechanism behind IL-7-induced thymic regeneration lies in its ability to enhance the proliferation of lymphocytes and lymphoid precursors. Administration of IL-7 resulted in T-cell proliferation, increased T-cell numbers, and increased TCR diversity both in animal models and in humans [149,151]. Initial clinical trials with recombinant human IL-7 (r-hIL-7) demonstrated an expansion of CD4$^+$ and CD8$^+$ T cells in patients with solid tumors or HIV infection [152–154]. A recent phase I trial of r-hIL-7 in recipients of T-cell-depleted allogeneic HCT showed that r-hIL-7 was well tolerated and induced a rapid increase in peripheral CD4$^+$ and CD8$^+$ T cells [93]. R-hIL-7 also resulted in increased TCR diversity and the generation of functional viral-specific CD8$^+$ T cells in transplants recipients.

Administration of KGF has been found to increase significantly thymic cellularity in aged mice and following radiation or chemotherapy [155–157]. KGF, which induces proliferation and expansion of thymic epithelial cells [158], can also protect TECs from GVHD-mediated thymic damage [157]. Although KGF has been approved for prophylactic treatment of mucositis in recipients of high-dose chemotherapy (including HCT), at present no clinical data exist regarding the potential of KGF to enhance T-cell reconstitution in patients.

The use of GH has also been proposed as a possible regenerative therapy. Treatment with exogenous GH regenerates the aged thymus [159] and enhances HPC function in the BM [160]. GH has also been shown to reverse irradiation-associated loss of BM function determined by colony formation [160]. The clinical experience with GH and T-cell recovery is limited to studies in HIV patients but has been demonstrated to enhance thymus function and anti-viral responses significantly [161,162].

Several other cytokines and growth factors have been evaluated for a beneficial role in regenerating the immune system. These include IGF-1, which promotes TEC expansion and enhances reconstitution following HCT [163]; IL-22, which promotes epithelial proliferation and survival in the thymus [84]; IL-15, which predominantly promotes proliferation of circulating NK and T cells [164]; and IL-12, which stimulates thymic expression of IL-7 and enhances hematopoietic engraftment after transplant [165]. IL-12 and IL-15 have also been found recently to act on regulatory lymphoid-tissue inducer cells and NK cells [166,167]. Furthermore, preclinical studies have shown that administration of Flt3L can also enhance both thymic-dependent and -independent T-cell reconstitution [168,169]. The effects of Flt3L are predominantly due to an expansion in Flt3$^+$ progenitors in the BM [170]. However, increases in T-cell reconstitution can be at the expense of B lymphopoiesis, which is significantly decreased with exogenous Flt3L administration and, in particular, its effects on BM progenitors [171].

Hormone therapies

As sex steroids have been implicated in the degeneration of thymopoiesis [172,173], B lymphopoiesis [174], and early lymphoid precursors [175], sex steroid ablation (SSA) has been investigated for its potential to enhance immune reconstitution. SSA can be achieved pharmacologically by disrupting upstream hormone signals, blocking the binding of sex steroid receptors, or inactivating the hormones themselves. SSA leads to reorganized thymic architecture and an enhanced ability to import circulating progenitors [176], and subsequently enhances thymopoiesis in aged mice and humans [35,177,178]. The effects of SSA, however, are not restricted to the thymus with enhanced B lymphopoiesis and lymphoid progenitors [179,180] also observed, in addition to enhancing overall immune recovery following autologous [181] and allogeneic [182,183] HCT and also cytoablative therapy [28,35,180]. In fact, SSA has been demonstrated to improve thymic function in prostate cancer patients, who routinely receive treatment with a luteinizing hormone-releasing hormone (LHRH) agonist, and also recipients of auto- and allo-HCT, in a dedicated phase I trial [92].

Cellular therapies

Given that some of the delay in immune reconstitution is due to the time it takes for a transplanted HSC to develop into a naïve lymphocyte, several groups have attempted to enhance immune rejuvenation by isolating and co-transplanting BM-derived lymphoid precursors [184]. However, this approach was severely limited by the supply of lymphoid progenitors. The advent of an ex vivo system for generating T cells using Notch-1 stimulation allowed the development of large numbers of T-lineage precursors that could be used for adoptive therapy [185,186]. Adoptive transfer of T-cell precursors into lethally irradiated allo-HCT recipients significantly enhanced thymopoiesis and chimerism, translating into enhanced peripheral T-cell reconstitution [185]. Moreover, recent studies have indicated that precursor T cells can develop into functional T cells even in the absence of a thymus [21,22]. In addition to their significant benefit for immune regeneration following transplant, in vitro-generated pre-T cells can also be genetically engineered for tumor specificity and subsequently used for targeted tumor immunotherapy [187]. Importantly, precursor T cells could be transferred across MHC barriers and develop into host-tolerant and fully competent T cells [187].

In addition to these therapies to boost the immune system that is already present, given the deterioration of the thymus with age and after repeated cytoreductive treatments, several strategies concentrate on building an entirely new thymus for regenerating immunity [188,189]. Although these strategies are still in their preclinical infancy, this can potentially be achieved by using endogenous thymic epithelial progenitor cells (TEPCs) that, in early development, can give rise to an entire thymus [190,191]. The identity and existence of a similar population in the adult thymus have so far remained elusive [192,193]. However, this could be moot, as a recent study has directed the reprogramming of thymic epithelial cells into functional multipotent skin stem cells [194]. A reverse of this approach, by reprogramming skin epithelium into TEPCs, would offer an excellent opportunity either to regenerate the thymus by grafting TEPCs directly or for the generation of an ex vivo transplantable thymus. Another alternative approach that has recently been achieved is to direct induced pluripotent stem cells towards a TEPC lineage. This approach has been shown to aid thymic reconstitution after allo-HCT [195].

Combination therapies

The extensive cross-talk that occurs between the thymic stromal compartment and developing hematopoietic cells [16] suggests that a combination of strategies could offer a greater regenerative boost than could be achieved by use of individual therapies alone. Preclinical studies using KGF have demonstrated that it can be used effectively in conjunction with other regenerative therapies, successfully enhancing the sole regenerative benefits of pre-T cells [185], SSA [31], and temporary inhibition of p53 [196]. However, it is unlikely that IL-7 could be used effectively in combination with KGF or SSA, as both of these strategies promote intrathymic production of IL-7 and studies in knockout mice have demonstrated that both of these regenerative strategies are dependent on IL-7 [155,182]. Another potentially useful combination strategy would be to combine therapies acting on the thymus with those acting on prethymic lymphoid progenitors. In fact, the rationale for this approach has been bolstered by recent studies that suggest that the supply of BM-derived lymphoid precursors limits thymic reconstitution after HCT [197].

Conclusion

HCT is associated with delays in immune recovery that have a significant impact on post-transplant morbidity and mortality from infections and relapse. Post-transplant immune deficiency is due to a variety of factors, including age-dependent thymic involution, conditioning-induced thymic damage, thymic GVHD, GVHD prophylaxis including in vivo or ex vivo T cell depletion, and treatment with immune-suppressive drugs. We have made significant progress in our understanding and monitoring of post-HCT immune recovery. With the introduction of new technologies such as deep sequencing, we are able to obtain information not only on TCR diversity but also on the frequency of specific clonotypes over time. Finally, new strategies are under development to enhance post-transplant T-cell recovery and several of those are now in clinical strategies, such as IL-7, KGF, SSA, and GH.

CHAPTER 16

Biology of the Human Graft-versus-Tumor Response and How to Exploit It

Edus H. Warren
Fred Hutchinson Cancer Research Center and Department of Medicine, University of Washington, Seattle, WA, USA

Defining characteristics of the graft-versus-tumor effect in human allogeneic hematopoietic cell transplantation

The principle that immune cells derived from the donor could contribute to the eradication of leukemia after allogeneic bone marrow transplantation (BMT) was initially established in murine models [1,2]. A graft-versus-tumor (GVT) effect operating in human allogeneic transplantation and associated with the development of acute and chronic graft-versus-host disease (GVHD) was subsequently identified in retrospective analyses of relapse rates following allogeneic hematopoietic cell transplantation (HCT) with high-intensity conditioning regimens for advanced leukemia [3,4]. Three independent lines of evidence have subsequently confirmed the existence of the GVT effect. First, complete regression of malignant disease after discontinuation of immune suppression has frequently been reported in patients whose tumors recurred after allogeneic HCT. Remissions induced by withdrawal of post-transplant immune suppression have been observed in patients with acute lymphoblastic leukemia (ALL), acute myeloid leukemia (AML), chronic myelogenous leukemia (CML), chronic lymphoid leukemia (CLL), Burkitt lymphoma, diffuse large B-cell and follicular non-Hodgkin lymphoma, multiple myeloma, ovarian cancer, and non-small cell lung cancer [5–7]. Second, infusions of lymphocytes harvested from the original hematopoietic cell donor have successfully been used to treat post-transplant persistence or recurrence of a comparably broad array of malignancies [8,9]. The antitumor activity of donor lymphocyte infusion (DLI) is most effective against CML that recurs in chronic phase after allogeneic HCT, but has also been observed in many patients with other kinds of leukemia, non-Hodgkin lymphoma, and multiple myeloma. Third, allogeneic HCT with reduced-intensity conditioning regimens that permit stable engraftment of donor hematopoietic cells but have little, if any, direct tumoricidal activity has produced durable complete remissions of advanced hematologic malignancies and selected solid tumors, including metastatic renal cell carcinoma, metastatic colon carcinoma, and metastatic breast carcinoma.

Three defining characteristics of the GVT effect were identified in retrospective analyses of relapse rates following HCT with bone marrow grafts from human leukocyte antigen (HLA)-identical sibling donors for early-stage or for advanced leukemia [3,4,10–14], and have subsequently been extensively confirmed in other transplant settings. By comparing the relapse rates seen in patients who developed no GVHD, acute GVHD, chronic GVHD, or both acute and chronic GVHD, it can be inferred that the GVT effect is strongly associated with the development of GVHD (Figure 16.1). However, comparison of the relapse rate observed in HLA-matched allogeneic HCT recipients who did not develop acute or chronic GVHD with that observed in recipients of HCT from syngeneic donors demonstrated that there is an antileukemic effect of allogeneic HCT per se that is independent of clinically significant GVHD. Finally, comparison of the relapse rate seen in HLA-matched allogeneic HCT recipients who received unmodified, i.e., T-replete, bone marrow grafts with that observed in recipients of allogeneic grafts from which T cells had been depleted prior to infusion revealed that the antileukemic effect associated with allogeneic HCT is impaired by removal of T cells from the bone marrow graft.

Identifying the genetic determinants, effector cells, and target molecules of the GVT effect

Autologous and syngeneic HCT

Although the term “GVT effect” as commonly used tacitly implies an antitumor effect that develops in the setting of *allogeneic* HCT and is mediated by donor-derived cells, it is possible that a GVT effect might also occur in the setting of autologous or syngeneic HCT. Identification of putative GVT activity associated with autologous or syngeneic HCT and mediated by cells contained in or derived from the autologous or syngeneic hematopoietic cell graft has been difficult owing to the lack of appropriate controls. In theory, graft-derived immune cells directed at tumor-specific or tumor-associated antigens could mediate GVT responses in the autologous or syngeneic HCT setting. Examples of potential tumor-specific or -associated antigens include the BCR/ABL fusion protein expressed in CML, the PML/RARα fusion protein expressed in acute promyelocytic leukemia, and proteins such as WT1 and proteinase 3 (PR3) that are overexpressed in both myeloid and lymphoid leukemias. The demonstration that the relapse rate after identical twin transplantation is inversely correlated with the nucleated cell dose in the syngeneic graft suggested, albeit weakly, that GVT activity may, indeed, occur after syngeneic HCT [15]. Humoral and $CD8^+$ T-cell immune responses to proteins expressed at high levels in myeloma cells were detected in one patient with multiple myeloma who achieved a complete remission following syngeneic HCT, but the antitumor contribution of these responses was unclear [16]. To date, little experimental evidence for a significant spontaneous antitumor

effect mediated by graft-derived immune cells after either autologous or syngeneic HCT has been reported.

Stimulation or potentiation of GVT activity in autologous or syngeneic hematopoietic cell grafts has been evaluated in numerous clinical trials. Post-transplant administration of Interleukin-2 (IL-2) without or with ex vivo-activated autologous effector cells was extensively evaluated in the autologous HCT setting [17], with inconsistent clinical results. An attempt to stimulate GVT activity in syngeneic HCT recipients based on adoptive transfer of donor lymphocytes and killed autologous leukemic cells, in order to immunize the infused donor lymphocytes against the autologous tumor, was associated with long-term disease-free survival in a small subset of treated patients [18]. The contribution of immunotherapy with donor cells and autologous tumor to the clinical outcome could not, however, be assessed. Studies in rodent models have demonstrated that administration of cyclosporine after autologous or syngeneic HCT can induce an autoimmune syndrome, termed syngeneic GVHD, with acute and chronic phases that closely resembles GVHD seen after allogeneic HCT [19]. The autoreactive effector lymphocytes in rodent syngeneic GVHD show promiscuous recognition of major histocompatibility complex (MHC) class II determinants, and can recognize and eliminate some MHC class II-expressing tumor cells. These preclinical studies consequently prompted clinical trials of cyclosporine administration after autologous or syngeneic HCT to induce syngeneic GVHD and enhance antitumor activity [20]. Although many patients in these trials did develop signs of GVHD, the induced GVHD was not associated with superior antitumor responses. In recent years, interest in potentiating GVT activity after autologous or syngeneic HCT has increasingly focused on stimulating T-cell responses against tumor-specific or tumor-associated antigens encoded by genes that are over- or aberrantly expressed in the recipient's tumor cells. In general, these antigens are also potential targets for immune therapy after allogeneic HCT, and will therefore be discussed in that context.

Allogeneic HCT

The critical genetic determinants, effector cells, and target molecules of the GVT effect associated with allogeneic HCT are strongly influenced by the degree and nature of genetic disparity between donor and recipient, the source, composition, and processing of the hematopoietic cell graft, and the recipient tumor type. Considerable evidence suggests that donor $CD4^+$ and $CD8^+$ T cells recognizing peptide–MHC complexes on the surface of recipient cells are the central mediators of GVT activity in HCT recipients who receive T-replete grafts from MHC-matched donors. Although there is no direct evidence as yet that donor natural killer (NK) cells contribute significantly to GVT in this setting, accumulating circumstantial evidence suggests the possibility of an NK contribution to GVT activity, particularly in patients with myeloid leukemias. In contrast, numerous studies suggest that donor NK cells are likely to play a central role in GVT responses that occur in recipients of hematopoietic cell grafts from MHC-mismatched donors, particularly if the degree of MHC mismatch requires the in vivo or in vitro depletion of T cells from the donor hematopoietic cell graft in order to prevent lethal GVHD. The characteristics of GVT responses in the MHC-matched and MHC-mismatched settings are therefore discussed separately, below.

GVT in haploidentical and MHC-mismatched HCT

For those patients for whom no MHC-matched donor can be identified, hematopoietic cell grafts from haploidentical related donors can be considered. To lower the risk of severe GVHD, such grafts are usually extensively depleted of T cells prior to infusion ($\sim 1 \times 10^4$ $CD3^+$ cells/kg), or the recipients are treated with agents such as cyclophosphamide or antithymocyte globulin in the early post-transplant period to deplete donor T cells in vivo. (HCT from haploidentical related donors is discussed more extensively in Chapter 46.) Pioneering work performed by the transplant group in Perugia, Italy, demonstrated that relapse after haploidentical HCT was infrequent when donor NK cells reactive with recipient malignant cells could be identified in the recipient post-transplant [21,22]. This observation led to an algorithm for predicting donor NK alloreactivity in haploidentical HCT that was based on donor–recipient MHC genotypes and whether these genotypes predicted incompatibility for a class of lymphocyte receptors encoded in the KIR (killer-cell immunoglobulin-like receptor) locus on chromosome 19q. Genes in the KIR locus encode transmembrane receptors that are expressed in NK cells and subsets of $\alpha\beta$ or $\gamma\delta$ T cells, bind to specific subsets of MHC class I alleles in a manner that is influenced by MHC-bound peptide [23,24], and participate in specific recognition of target cells by NK and T cells. The analysis performed by the Perugia team revealed that predicted donor–recipient incompatibility for the subset of KIR receptors with *inhibitory* function was strongly associated with lower risk of relapse. Functional analysis of donor NK clones from the subset of transplant pairs with incompatibility for inhibitory KIR – defined as the presence of donor NK cells that expressed as their sole inhibitory KIR a receptor for an MHC class I specificity that was expressed by the donor but absent in the recipient, termed "missing self" recognition – also revealed potent in vitro cytotoxicity against recipient lymphocytes, dendritic cells, and leukemic blasts. Moreover, the NK cytotoxicity was demonstrable primarily against lymphohematopoietic cells – including human leukemia engrafted in NOD/SCID (non-obese diabetic/severe combined immunodeficiency syndrome) mice [22] – and not against nonhematopoietic cells, which was thought to explain the potent GVT activity observed in the absence of clinically significant GVHD. A surprising finding in these groundbreaking studies was the observation that GVT activity associated with donor NK alloreactivity in haploidentical HCT was far more effective against myeloid than against lymphoid leukemia, a finding that to date has not been entirely explained. It is likely that ALL cells do not frequently express the cognate ligand for one or more *activating* receptors expressed by alloreactive donor NK cells, appropriate ligation of which is also thought to be required for the activation of NK cytotoxicity [25].

The important role of donor NK alloreactivity in T-cell-depleted haploidentical HCT has been confirmed in many studies, and has prompted the formulation of several clinical algorithms for predicting donor NK alloreactivity in this [26,27] and other [28,29] transplant settings. An alternative to the "missing self" model, the "missing ligand" model, was proposed, which more broadly defines donor–recipient KIR incompatibility as the absence in the recipient of any MHC class I specificity for which donor NK cells express inhibitory KIR, regardless of whether the donor expresses that MHC specificity [26]. This model was used with some success to predict leukemic control – the proxy for GVT activity – in HCT recipients of T-cell-depleted grafts from MHC-matched siblings [28] and in recipients of grafts from unrelated donors [29], supporting a contribution of donor NK alloreactivity to GVT responses in these settings. Although it is still unclear whether the "missing self" or "missing ligand" model more accurately predicts donor NK alloreactivity in HCT recipients who receive T-cell-depleted grafts from matched or mismatched donors, substantial clinical and laboratory evidence supports an important role for alloreactive donor NK cells in GVT responses that occur in the T-depleted, haploidentical, or multiply MHC-mismatched HCT setting.

Analysis of leukemic blasts obtained from patients with recurrent AML or myelodysplastic syndrome (MDS) after haploidentical HCT has provided compelling additional support for the notion that donor lymphocytes with specificity for products of recipient MHC genes on the unshared haplotype are the primary mediators of GVT activity in this setting. Loss of the entire recipient MHC haplotype not shared by the donor, as a result of acquired uniparental disomy of chromosome 6p [30], was observed in leukemic blasts obtained from five of 17 patients who relapsed after haploidentical HCT followed by post-transplant infusion of donor T cells. Loss of the unshared recipient MHC haplotype, once again via a mechanism that involved acquired uniparental disomy, was also observed in leukemic blasts obtained from two of three children with AML who had relapsed after haploidentical HCT [31].

It is plausible that GVT activity in HCT recipients of T-replete or partially T-depleted grafts from MHC-mismatched donors could be mediated by alloreactive donor T cells, alloreactive donor NK cells, or both. Assessment of the relative contributions of donor T and NK cells to GVT activity in this setting is limited by a dearth of relevant clinical and laboratory data. It is likely that the contributions of donor T and NK cells are in part determined by the extent of T-cell depletion and the number and identity of MHC loci at which the donor and recipient are mismatched. In particular, donor T cells are likely to play the more important role in recipients mismatched for MHC class II but not class I alleles, because the specificity of NK cell alloreactivity is determined primarily by the MHC class I, but not class II, molecules expressed on their target cells [32,33]. GVHD and GVT reactions in recipients of T-replete grafts from donors mismatched at a single MHC class I [34,35] or class II [36] locus are typically dominated by donor T cells that are heavily biased towards reactivity with the mismatched recipient allele.

GVT in MHC-matched HCT

Donor–recipient disparity at genetic loci encoded within the MHC on chromosome 6p is the single most important risk factor for the development of severe, life-threatening GVHD after allogeneic HCT [37,38]. Consequently, most patients who undergo allogeneic HCT receive hematopoietic cell grafts from donors with whom they are either genotypically or phenotypically matched at the MHC. The increased relapse rate observed in recipients of T-depleted hematopoietic cell grafts from MHC-matched donors [10,12] indicates that donor T cells play a critical role in GVT responses after MHC-matched HCT. Studies in which CD8$^+$-depleted DLI from MHC-matched donors [39,40] was administered to patients with post-transplant relapse have demonstrated that CD4$^+$ T cells can mediate GVT activity. A role for CD8$^+$ T cells in human GVT has also been suggested by the observation of in vivo expansions of CD8$^+$ T cells with in vitro reactivity against recipient tumor cells during GVT reactions after HCT [41] or DLI [42–46]. A role for NK cells in GVT activity after T-replete MHC-matched HCT has been suggested by reports that donor KIR genotype is associated with risk for relapse in both related [47,48] and unrelated [49–51] pairs, but there is limited direct evidence that NK cells contribute to GVT in this setting [52,53], and some evidence to the contrary [54].

Minor histocompatibility antigens

GVHD and GVT activity occur in the majority of allogeneic HCT recipients who receive T-replete hematopoietic cell grafts from genotypically or phenotypically MHC-matched donors. Thus, GVHD and GVT can also be triggered by donor–recipient genetic disparity at polymorphic loci outside the MHC, which are consequently referred to as minor histocompatibility (minor H) loci. Studies in both mice [55,56] and humans [57,58] have demonstrated that minor H loci encode short peptides – termed minor H antigens – that are encoded by polymorphic genes encoded outside the MHC and presented on the cell surface by MHC class I and class II molecules, where they can be recognized by donor CD8$^+$ and CD4$^+$ T lymphocytes, respectively. CD8$^+$ T cells recognize peptides that are typically 8–11 residues in length and derived from the degradation of intracellular proteins by the proteasome, transported into the endoplasmic reticulum (ER) by the transporter associated with antigen processing (TAP), and delivered to the cell surface as a trimolecular complex with MHC class I molecules and β_2-microglobulin. CD4$^+$ T cells recognize peptides that are derived from lysosomal degradation of phagocytosed exogenous proteins or proteins produced endogenously within the cell, and delivered to the cell surface as a complex with heterodimeric MHC class II molecules. Peptides associated with MHC class II molecules tend to be longer than those associated with MHC class I, due to the more "open" configuration of the ends of the peptide-binding groove in the class II heterodimer. Donor T-cell responses to minor H antigens presented on the surface of recipient cells are thought to be the central mediators of both GVHD and GVT activity.

Molecular characterization of minor H antigens

CD8$^+$ and CD4$^+$ T cell clones specific for minor H antigens presented by MHC class I and class II molecules, respectively, can be isolated from most HCT recipients of T-replete grafts [59]. Biochemical and genetic techniques have been used to identify the genes that encode human minor H antigens recognized by T-cell clones from HCT recipients, and to define the nature of the polymorphism in these genes (for a review, see [60]). Global collaborative initiatives in human genetics such as the HapMap Project [61–63] and the 1000 Genomes Project [64] have greatly accelerated the identification and characterization of minor H antigens. As of early 2013, at least 50 different genes that encode minor H antigens recognized by either CD8$^+$ or CD4$^+$ T cells have been identified (Figure 16.2). Although most of these genes are located on autosomes, with virtually every chromosome represented, at least six different genes on the Y chromosome encode male-specific minor histocompatibility (H-Y) antigens. Both sequence variation and structural variation in the human genome can give rise to minor H antigens. Many autosomally encoded minor H antigens are created by non-synonymous single nucleotide polymorphisms (nsSNPs) in protein coding sequences that give rise to immunogenic single amino acid polymorphisms. The prototypic minor H antigen HA-1, for example, is created by an nsSNP in the *HMHA1* gene that in turn creates a His⇔Arg amino acid polymorphism in its protein product [65]. A peptide derived from the antigenic allele of *HMHA1* that spans this polymorphism, VL***H***DDLLEA, binds to HLA-A*02:01 (Figure 16.3), but the homologous peptide encoded by the other allele, VL***R***DDLLEA, binds only weakly to HLA-A*02:01 and dissociates from it very rapidly [66,67]. CD8$^+$ T-cell responses specific for the VLHDDLLEA peptide presented by HLA-A*02:01 frequently occur in HLA-A*02:01$^+$ donor–recipient HCT pairs that are discordant – or "mismatched" – for the antigenic allele, that is, the recipient is positive and the donor negative. In addition to affecting the binding of peptides derived from self proteins to MHC molecules, amino acid polymorphisms created by nsSNPs can alter how such peptides are generated inside the proteasome [68], transported into the ER by TAP, the *t*ransporter associated with *a*ntigen *p*rocessing [69], or are recognized by T cells when presented on the cell surface in a complex with MHC [70].

Although most minor H antigens are created by nsSNPs in consensus protein sequences, variation in the human genome can also create minor H antigens in other ways. SNPs in autosomal genes, for example, can create minor H antigens by generating stop codons [71] or by altering mRNA splice sites [72,73]. A single nucleotide insertion–deletion polymorphism in the *P2RX5* gene that shifts reading frame was shown to create a minor H antigen [74]. Some

Figure 16.2 Map of genetic loci that can influence histocompatibility in the allogeneic HCT setting. The chromosomal location of the MHC, and of two other multigene clusters, the NKC and the *KIR* locus, are indicated by single-underlined labels and arrowheads to the left of the corresponding chromosomes. The chromosomal locations of genes that have been shown to encode T-lymphocyte-defined minor histocompatibility antigens are indicated by labels and arrowheads to the right of the corresponding chromosomes; genes that encode class I MHC-restricted minor H antigens recognized by CD8$^+$ T cells are indicated by black labels, those that encode class II MHC-restricted minor H antigens recognized by CD4$^+$ T cells are indicated by double-underlined labels, and those that encode both class I and class II MHC-restricted minor H antigens are indicated by boxed labels. Figure 16.3 (Top) Structure of HLA-A*02:01 with the peptide VLHDDLLEA, the minor histocompatibility antigen HA-1, bound in its peptide-binding groove. The HLA-A*02:01/HA-1 peptide structures were derived from Protein Data Bank accession No. 3D25 [66], and was rendered with PyMOL [173]. (Bottom) The nucleotide sequence of the antigenic and non-antigenic alleles of the *HMHA1* gene in the interval that spans the nsSNP that creates the HA-1 minor H antigen, and their corresponding peptide sequences.

minor H antigens are encoded by SNPs that are not located in consensus protein-coding genes. Several autosomal minor H antigens, for example, are created by SNPs in cryptic, non-canonical open reading frames such as *HMHB1* [70] and *C19orf48* [75] from which no protein product has been identified. Another minor H antigen is encoded in the nominal 3′ "untranslated" region of a protein-coding gene [76]. Variation in genome structure can also give rise to minor H antigens. The *UGT2B17* gene on chromosome 4q is homozygously deleted in a fraction of every human population that has been studied to date [77,78]. Peptides derived from the UGT2B17 protein can serve as minor H antigens in donor–recipient pairs in which one member of the pair expresses the gene but the other is homozygously deleted [79]. Minor H antigens derived from UGT2B17 and presented by HLA-A*29:02, HLA-B*44:03, and HLA-A*02:06 have been identified, and it is likely that additional UGT2B17-derived peptides can bind to additional MHC alleles and serve as minor antigens.

Male-specific minor H antigens

A small class of genes on the Y chromosome has been shown to encode male-specific minor H (H-Y) antigens that are targets for female T cells in sex-mismatched transplants. The genes in this class are distinguished from most other Y chromosome genes by the fact that they have X chromosome homologues that encode proteins that are 81–99% identical in sequence with the Y-encoded isoforms, and they are expressed both in and broadly outside the testis [80,81]. This class of genes is likely derived from the ancestral autosome(s) from which the human X and Y chromosomes evolved [81]. The extensive sequence disparity between the protein products of these Y chromosome genes and the protein products of their X chromosome homologues creates a large number of male-specific peptides that could potentially serve as targets for female T cells in an MHC-matched HCT setting. Moreover, the extra-testicular expression of these genes allows the presentation of these peptides to the female system outside the immunologic sanctuary of the testis. The immunologic significance of H-Y antigens is likely enhanced by the fact that the Y chromosome is inherited as a single functional genetic element, and therefore all H-Y antigens are in complete linkage disequilibrium. More than 25 human H-Y antigens have been identified to date, and it is likely that more remain to be identified.

Expression of minor H antigens in normal tissues and leukemia

Assessment of the expression profile of minor H antigens in normal and malignant tissues has provided insight into the potential contributions of minor H antigen-specific T-cell responses to GVT activity. Many minor H antigens are expressed in both hematopoietic and non-hematopoietic cells in vitro [59,82], suggesting that T-cell responses to these antigens could contribute to both GVT and GVHD. However, a significant fraction of minor H antigens show expression that is limited to cells of hematopoietic origin [59,82,83], raising the prospect that T-cell responses against these minor antigens might contribute selectively to GVT activity. In addition, $CD4^+$ and $CD8^+$ T-cell clones specific for minor H antigens that are selectively expressed in hematopoietic cells recognize lymphoid and myeloid leukemic cells in vitro [59,83–86], and inhibit the growth of clonogenic leukemic cells in in vitro culture [85,86]. $CD8^+$ minor H antigen-specific cytotoxic T-lymphocyte (CTL) clones also inhibit the engraftment of human acute leukemia into NOD/SCID mice [87], demonstrating that leukemic stem cells express minor H antigens and can be targeted by minor H antigen-specific CTL.

Contributions of minor H antigen-specific T-cell responses to GVT

Cellular and molecular dissection of immune responses occurring in HCT recipients after HCT or DLI has provided compelling evidence that minor H antigens expressed on recipient leukemic cells are targets of GVT responses in MHC-matched HCT. Serial flow cytometric analysis with MHC tetramers complexed with minor H antigen peptides to detect and enumerate minor H antigen-specific T cells in the blood of HCT recipients has demonstrated that minor H antigen-specific T cells with in vitro reactivity against recipient leukemic cells increase in frequency in the peripheral blood before and during clinical regression of malignancy. A large in vivo expansion of $CD8^+$, MHC/peptide $tetramer^+$ T cells specific for an H-Y antigen encoded by the Y chromosome gene *KDM5D* and presented by HLA-A*02:01 [88] was observed in a male HLA-A*0201^+ patient who had received a graft from his MHC-identical sister, and this expansion was temporally correlated with achievement of molecular remission of CML in blast crisis [41]. At the peak of the response, $tetramer^+$ cells comprised 15.9% of the $CD8^+$ T cells in peripheral blood. MHC/peptide $tetramer^+$ T cells isolated and purified by flow cytometry demonstrated in vitro cytotoxicity against the recipient's leukemic blasts. Similar studies of GVT reactions occurring in patients with persistence or recurrence of malignancy after HCT who underwent DLI have identified expansions of MHC/peptide $tetramer^+$ cells specific for several other minor H antigens. In vivo expansions of $CD8^+$ T cells recognizing the HLA-A*02:01-restricted HA-1 and HA-2 minor H antigens encoded by the *HMHA1* [65] and *MYO1G* [57,89] genes, respectively, that were temporally correlated with clinical responses to DLI have been observed in HLA-A*$02:01^+$ patients with Ph^+ ALL or CML [43,45,90,91]. $CD8^+$ T-cell responses to minor H antigens encoded by *P2RX5* [74] and by *TRIP10*, *SWAP70*, *SON*, and

NUP133 [76] were demonstrated in other CML patients responding to DLI. Cloned minor H antigen-specific T cells from these patients specifically recognized $CD34^+$ leukemic progenitor cells in vitro. A $CD8^+$ T-cell response to a minor H antigen encoded by the *C12orf35* gene that coincided with achievement of remission after DLI was similarly observed in a multiple myeloma patient [92]. Minor H antigen-specific T cells may also contribute to regression of solid tumors after MHC-matched allogeneic HCT. Extensive regression of metastatic renal cell carcinoma (RCC) was observed in one patient after three separate infusions of donor lymphocytes followed by initiation of interferon-α [75,93]. $CD8^+$ CTL clones recognizing multiple distinct minor H antigens presented by RCC cells were isolated from patient peripheral blood mononuclear cells obtained during and after tumor regression, including $CD8^+$ T cells specific for the HA-1 minor antigen. The observation of HA-1 expression, which in non-malignant cells is limited to the hematopoietic lineage [82], in primary RCC cells is consistent with previous studies that demonstrated aberrant expression of HA-1 on solid tumor cell lines of epithelial origin [94,95].

Although tetramer-based analyses have demonstrated that clinical GVT activity is associated with T-cell responses against specific minor H antigens, it is likely that the GVT effect in most patients comprises simultaneous responses against multiple different target antigens – likely more than can be simultaneously monitored with tetramer-based techniques. Serial analysis of the peripheral blood T cell repertoire in CML [96] or multiple myeloma [97] patients responding to DLI with $CD4^+$-selected cells from MHC-matched sibling donors revealed the appearance of multiple distinct clonal T-cell populations that was temporally correlated with GVT activity. Moreover, complete responses observed in several CML patients after $CD4^+$-selected DLI were associated with in vivo expansion of $CD8^+$ T cells recognizing a number of novel, as yet uncharacterized, minor H antigens expressed on recipient hematopoietic cells [42]. In vivo expansion of $CD8^+$ T cells recognizing myeloma-specific antigens was observed in multiple myeloma patients responding to $CD4^+$-selected DLI [44]. Direct cloning of interferon-γ-secreting peripheral blood T cells from three multiple myeloma or CML patients responding to unselected DLI led to the identification of $CD8^+$ T-cell clones recognizing multiple distinct minor H antigens [46], and analysis of a CML patient who responded to DLI identified simultaneous $CD8^+$ T-cell responses against four different HLA-B*40:01-restricted minor antigens [76].

Numerous retrospective analyses of MHC-matched transplant outcome have attempted to evaluate the contribution of minor H antigen-specific T cells to GVT activity by correlating donor–recipient genetic disparity at specific minor H loci with post-transplant relapse or remission of disease. The studies that focused on disparity at autosomal minor H antigens generally had inconsistent results, but the largest of these showed no significant correlation between donor–recipient disparity at the loci encoding the *HA-1* [98], *HA-8* [99], or *UGT2B17* [100] loci and control of leukemia after HCT. The failure to demonstrate any such correlation is most likely attributable to the fact that the total number of minor H antigens is probably fairly large, and all donor–recipient pairs will be mismatched for scores if not hundreds of minor H antigens [60,64]. The clinical effect associated with disparity at any one locus will therefore account for a very small fraction of the total risk for relapse. In contrast, several large retrospective analyses of transplant outcome have identified a lower incidence of relapse in male recipients of female hematopoietic cell grafts (F→M HCT) compared with all other donor–recipient gender combinations, suggesting that, in the aggregate, T-cell responses to H-Y antigens have a clinically measurable antileukemic effect [101–103]. The lower incidence of relapse observed after F→M HCT is seen in patients transplanted for CML, AML, and ALL, and is apparent even after controlling for GVHD [102]. The expression of some H-Y antigens in leukemic stem cells [104] provides additional support for an H-Y contribution to GVT. The clinically measurable antileukemic effect associated with F→M HCT might, at first, seem surprising, given the lack of an identifiable antileukemic effect associated with donor–recipient disparity at any single autosomal minor H locus. However, this seeming paradox is readily resolved by the recognition that (1) the human Y chromosome contains at least 15 genes with the potential to encode minor H antigens [80,81], (2) each of these genes can potentially encode several distinct H-Y antigens, due to the extensive sequence disparity between their protein products and those of their X chromosome homologues, (3) the H-Y genes encode both MHC class I- and class II-restricted H-Y antigens, and (4) all H-Y antigens are in complete linkage disequilibrium. Therefore, in any female donor–male recipient HCT pair, the Y chromosome has the potential to stimulate a diverse repertoire of $CD8^+$ and $CD4^+$ T-cell responses to many distinct minor H antigens.

HLA-DP as a target for GVT responses in unrelated donor HCT

Alloreactive $CD4^+$ donor T cells specific for recipient HLA-DP molecules likely make a specific contribution to GVT activity in patients with $HLA\text{-}DP^+$ malignancies who receive grafts from unrelated donors. Although most related donor–recipient HCT pairs who are matched at *HLA-A*, *-B*, *-C*, *-DRB1*, and *-DQB1* are also matched at *HLA-DP* [60], several large retrospective studies have shown that most (~80%) unrelated donor–recipient pairs are mismatched for one or two HLA-DP alleles [105–107]. Donor–recipient mismatch at HLA-DP in these studies was consistently associated with a significantly reduced incidence of post-transplant relapse. Analysis of recipient-specific T-cell responses in patients with $HLA\text{-}DP^+$ malignancies who responded to DLI from HLA-DP mismatched unrelated donors has provided compelling direct evidence that donor $CD4^+$ T cells specific for the mismatched recipient HLA-DP alleles can have potent antitumor activity in this setting [108].

T-cell responses to non-polymorphic tumor-associated antigens

Accumulating evidence indicates that non-polymorphic antigens encoded by genes that are aberrantly or over-expressed in myeloid and lymphoid leukemic cells are also targets of T-cell responses that contribute to GVT after MHC-matched HCT. $CD8^+$ CTL specific for an HLA-A*0201-restricted peptide termed PR1 that can be derived from both PR3 and elastase were detected at increased frequency in the blood of several HLA-A*$02{:}01^+$ CML patients who achieved remission after MHC-matched HCT [109]. PR3, also known as myeloblastin, and elastase are both major constituents of the primary azurophil granules of normal promyelocytes and also AML and CML blasts. PR1-specific CTLs recognize myeloid leukemia cells in vitro [110] and inhibit the growth of CML colony-forming units [111]. High levels of PR3 or elastase expression in $CD34^+$ myeloid progenitor cells in patients with advanced-phase CML are also associated with improved outcome after allogeneic HCT [112].

The protein products of several other non-polymorphic genes that are selectively or exclusively expressed in malignant cells can also serve as targets for post-transplant GVT responses. CD8$^+$ T cells specific for peptides derived from the WT1 protein were detected in five out of ten ALL patients in one series [113]. WT1-specific CTL were only detected in those recipients in whom *WT1* expression was detected pre-transplant, and emergence of WT1-specific CTL post-transplant was associated with a decrease in *WT1* expression in the bone marrow. Cancer-testis antigens are occasionally expressed in hematologic malignancies, particularly in advanced multiple myeloma, and CD8$^+$ and CD4$^+$ responses to cancer-testis antigens such as NY-ESO-1 [114] and several members of the MAGE family [115] have been detected after MHC-matched HCT for multiple myeloma and also acute leukemia. Donor T-cell responses against tumor-specific antigens also develop in patients with solid tumors who undergo allogeneic HCT. A potent tumor-specific CD8$^+$ T-cell response directed against an antigenic peptide encoded by human endogenous retrovirus type E was detected in a patient with metastatic RCC who achieved a durable complete remission after non-myeloablative MHC-matched HCT [116].

NK contributions to GVT in MHC-matched HCT

Provocative indirect evidence suggests a role of donor NK cells in mediating GVT after MHC-matched HCT. Several retrospective analyses have demonstrated significant associations between the relapse rate of myeloid leukemias, donor and recipient MHC genotype, and donor KIR haplotype and gene content, in both related [28,48,117] and unrelated [29,49–51,118] HCT pairs. The KIR genes are both polymorphic and highly homologous with one another, and the gene content of the KIR locus on chromosome 19q is itself polymorphic. Two basic types of KIR haplotypes – termed A and B – distinguished primarily by their content of genes for activating receptors have been identified (Figure 16.4). The largest and most compelling studies of MHC and KIR genotype and post-transplant relapse have shown significant associations between the presence in the donor of a type B KIR haplotype, or one or more components thereof – possibly the *KIR2DS1* gene that encodes an activating NK receptor – and decreased rate of relapse in recipients undergoing unrelated HCT for AML and other myeloid neoplasms [49–51]. High levels of donor NK chimerism in the early post-transplant period have been associated with a lower rate of relapse in recipients of non-myeloablative HCT [119]. Although much remains to be learned about the cellular and molecular basis of these associations, they are consistent with the notion that alloreactive donor NK cells may mediate antitumor activity in recipients of HCT from MHC-matched donors.

B-cell contributions to GVT

Analysis of sera obtained from allogeneic HCT recipients has revealed that donor-derived humoral responses to polymorphic and non-polymorphic antigens expressed by recipient cells occur commonly in HCT recipients, and in some cases may contribute to GVT. The possibility of antibody responses to H-Y proteins was first suggested in 1979, when immunoglobulin M antibodies were found in the serum of a heavily transfused female patient with aplastic anemia that were reactive mainly, but not exclusively, with cells from male donors [120]. Analysis of males undergoing F→M HCT has subsequently demonstrated that high-titer IgG responses against Y chromosome proteins can be detected in approximately 50% of cases [121,122]. Mapping the fine specificity of H-Y-specific antibodies has demonstrated a strong bias towards regions of Y chromosome proteins where there is non-identity with the products of their X chromosome-encoded homologues [121], consistent with the antigenic specificity of H-Y T-cell responses. In a study of 121 HCT patients and 134 healthy control individuals, antibodies reactive with the protein products of one or more of five Y chromosome genes – *DBY*, *UTY*, *ZFY*, *RPS4Y*, and *EIF1AY* – were detected in 52% of male patients with female donors but only 9% of male patients with male donors, and in 41% of healthy females but only 8% of healthy males [122]. The presence of antibody responses to one or more of the five Y chromosome genes was also strongly associated with the maintenance of disease remission, suggesting that humoral responses to Y chromosome gene products may be a marker for the selective graft-versus-leukemia effect observed in male recipients of MHC-matched female hematopoietic cell grafts [102].

SEREX (SErological identification of antigens by Recombinant cDNA EXpresson cloning) analysis of allogeneic HCT recipients responding to DLI has demonstrated that GVT activity is associated with humoral responses to proteins expressed in recipient tumor cells. HCT recipients who achieve complete remission of CML [123,124] and multiple myeloma [125,126] after DLI administered for treatment of persistent or recurrent disease make high-titer IgG responses to non-polymorphic antigens that are over- or aberrantly expressed in CML or myeloma cells. Although a large fraction of the humoral response is directed at molecules that are not known to be expressed on the cell surface, antibodies to B-cell maturation antigen (BCMA), which is expressed on the cell surface, were found only in post-DLI responder sera from multiple myeloma patients [126]. Serum containing anti-BCMA antibodies was able to induce

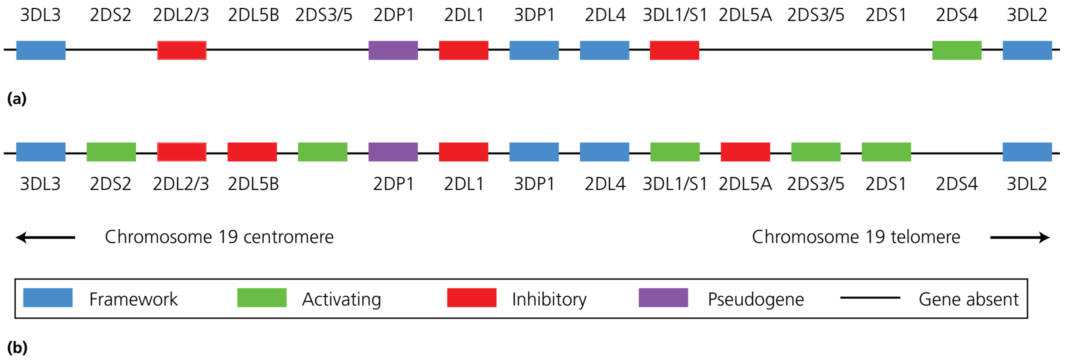

Figure 16.4 Basic organization and gene content of the human *KIR* locus on chromosome 19q. Two hypothetical haplotypes are illustrated: an A and a B haplotype. Framework genes (which can be coding genes or pseudogenes) are illustrated as boxes numbered 1, non-framework activating genes 2, inhibitory genes 3, and pseudogenes 4. Adapted from: EMBL-EBI, http://www.ebi.ac.uk/ipd/kir/sequenced_haplotypes.html, 2014. Reproduced with permission of EMBL-EBI.

complement-mediated lysis and antibody-dependent cellular cytotoxicity of a tumor cell line transfected with a *BCMA* cDNA, and also of primary myeloma cells expressing BCMA, suggesting that BCMA is a potential target of the GVT response in multiple myeloma. Antibodies to tumor-specific antigens such as NY-ESO-1 that are associated with donor NY-ESO-1-specific CD8$^+$ and CD4$^+$ T-cell responses have also been detected in myeloma patients after HCT [114]; whether these antibodies contributed to post-transplant graft-versus-myeloma activity, or simply served as a marker for it, is unknown.

Human genomic diversity and the number of minor H antigens

The advent of high-throughput DNA sequencing over the last half decade has allowed comprehensive exploration of human genetic variation in recent years. As the number of completely sequenced human genomes continues to grow at a nearly exponential rate, it is increasingly clear that genetic diversity both within and between human populations is far greater than was appreciated when the first reference genome was completed in 2000. Preliminary results of the 1000 Genomes Project, for example, have suggested that the genome of any individual will differ from the reference human genome sequence at 10,000–11,000 nsSNPs [64]; thus, by extension, the genomes of any two unrelated individuals will differ by a comparable number of nsSNPs. Concurrent advances in the detection of structural variation in the human genome (operationally defined as sequence variation of at least 50 bp in size [64]) have demonstrated that any two individual genomes will also differ at a large number of structurally variant sites. Indeed, it has been estimated that structural variants account for more heritable nucleotide sequence differences between individuals than SNPs (0.5–1% for structural variants and 0.1% for single nucleotide variants) [127].

The enormous extent of human genomic diversity has profound implications for efforts to understand how polymorphism in the genome can elicit immune responses that contribute to GVT, and also for efforts to exploit these immune responses to decrease relapse and improve HCT outcome. Extensive sequence and structural polymorphism in the genome implies that there are a very large number of protein and peptide sequences that, in the setting of MHC-matched allogeneic HCT, could potentially stimulate and serve as targets for donor T-, NK-, and B-cell responses that could mediate GVT activity. Dissection of GVT responses at the cellular and molecular level is, indeed, beginning to show that GVT in any one HCT recipient is likely to be mediated by an immune response with broad antigenic specificity that is directed at both polymorphic alloantigens and non-polymorphic over- or aberrantly expressed self antigens on recipient tumor cells. The diversity of this response is likely to be one of the keys to the remarkable potency of the GVT effect. Nonetheless, post-transplant persistence or recurrence of disease remains a major cause of treatment failure after allogeneic HCT, and developing a more comprehensive understanding of the GVT response is an urgent research priority. Recognition of the enormous diversity in the genome demonstrates that there is abundant polymorphism to be exploited, but also suggests that whole genome approaches to understanding GVT will likely provide the key to its successful exploitation.

Strategies for exploiting the GVT response

Early attempts to manipulate the GVT effect and decrease the relapse rate after allogeneic HCT were motivated by the recognition that GVT is mediated by cells contained in or derived from the hematopoietic cell graft, and that exogenous immune suppression, although it suppresses GVHD, also suppresses GVT. Complete omission of GVHD prophylaxis in the MHC-matched sibling BMT setting led to severe and hyper-acute GVHD, and the increase in GVHD-related mortality precluded the identification of any decrease in the relapse rate [128]. The prophylactic administration of donor buffy-coat cells after MHC-identical sibling BMT, with a standard course of methotrexate alone as GVHD prophylaxis, was also associated with an increased rate of severe, and often fatal, acute GVHD, and also prevented the detection of any effect on the relapse rate [129]. Characterization of T- and B-cell immune responses associated with GVT activity after HCT or DLI and identification of their antigenic targets has demonstrated that the targets of GVT and GVHD responses are not completely overlapping. Many current efforts to manipulate GVT are consequently focused on the development of therapeutic strategies for enhancing donor immune responses against defined antigens that are selectively or exclusively expressed on recipient tumor cells, and not widely expressed on tissues that are targets for GVHD. In addition, characterization of the extensive sequence and structural variation in the human genome has stimulated the search for novel polymorphic genetic loci that could potentially be exploited to enhance GVT activity.

Identifying genomic loci associated with GVT activity

The identification of extensive sequence and structural variation in the human genome suggests exciting possibilities for exploiting genomic diversity to enhance GVT, but also poses several challenging new questions. What fraction of the polymorphic loci in the genome can elicit T- or B-cell responses that can contribute to GVT? Are there specific autosomal loci at which donor–recipient disparity makes a measurable contribution to GVT activity? Are there genetic variants in the donor or the recipient that influence GVT activity in a manner that is independent of donor–recipient matching or mismatching? The advent of microarray-based genotyping technologies that permit simultaneous determination of SNP genotype and of copy number at millions of unique sites distributed throughout the genome has raised the prospect of using whole genome association analysis to address these questions in a comprehensive fashion. A genome-wide approach to the identification of loci associated with GVT could potentially facilitate the identification of polymorphic loci at which donor–recipient mismatching is significantly associated with decreased risk for relapse, and could identify genetic variants in the donor or in the recipient that, independent of donor–recipient matching or mismatching, are also associated with decreased relapse risk.

MHC genotypically identical sibling pairs represent a transplant population that is uniquely suited to the application of whole genome association analysis for the identification of loci associated with GVT activity. Full siblings share 50% of their genomes and, on average, are expected to be genetically identical for *both* alleles at 25% of their genomes. If relapse risk is in fact measurably influenced by donor–recipient disparity at specific autosomal loci, it is reasonable to hypothesize that HCT recipients who relapse post-transplant will, on average, show more genetic identity with their donors for both chromosomes at such putative "GVT loci" than recipients who do not relapse. Thus, in the case of MHC-identical siblings, where donors and recipients are selected for genetic identity for both alleles within the MHC, this hypothesis predicts that HCT recipients who relapse post-transplant will show *more* genetic identity for both alleles with their donors than the expected 25% at

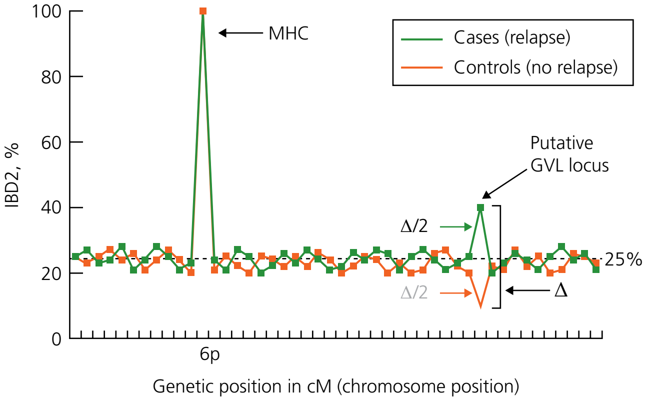

Figure 16.5 Identification of a putative "GVT locus" through assessment of donor–recipient genetic identity for both alleles at a large number of polymorphic loci distributed across the entire genome. MHC-identical sibling donor–recipient pairs are genotyped at hundreds of thousands of polymorphic loci distributed across the genome using high-density oligonucleotide arrays. Although the average fraction of donor–recipient pairs who have identical genotypes at any given polymorphic locus *outside the MHC* is expected to be 0.25, the observed fraction will fluctuate around this mean value. At a hypothetical "GVT locus," the observed fraction of donor–recipient pairs with identical genotypes in a population in which the recipient relapsed ("cases") is expected to be significantly higher than the observed fraction of pairs with identical genotypes in a population of pairs in which the recipient did not relapse ("cases"), with an effect size Δ.

GVT loci, and patients who do not relapse post-transplant will show *less* genetic identity for both alleles with their donors than the expected 25% (Figure 16.5). This hypothesis is currently being tested in a retrospective analysis of 3500 MHC-identical sibling donor–recipient pairs who underwent T-replete allogeneic HCT for the treatment of a myeloid malignancy at a single transplant center.

Donor selection

The current approach to selection of donors for patients requiring allogeneic HCT is focused on the identification of individuals who are identical with the intended recipient for sequences within exons 2 and 3 of the *HLA-A*, *-B*, and *-C* genes and also exon 2 of *HLA-DRB1* [130]. For those patients for whom several optimally matched donors can be identified, deliberate selection of a donor whose genotype at additional loci might confer an enhanced GVL benefit without an increased risk for GVHD would be desirable. For example, the results of several large retrospective studies have suggested that consideration of donor and recipient genotype at additional loci within the MHC – particularly the loci that encode the α and β chains of HLA-DP heterodimers – could potentially lead to improved transplant outcome [105–107,131]. For patients at low risk for post-transplant relapse, selection of a donor who is matched with the recipient at HLA-DP might provide benefit in the form of a lower risk for severe GVHD. In contrast, for those at high risk for relapse, deliberate selection of a donor who is mismatched with the recipient at HLA-DP could prove to be beneficial, as such mismatches are also associated with a reduced incidence of relapse [105,106,131]. Consideration of donor and recipient genotype at loci outside the MHC might also enhance the expected GVL benefit from allogeneic HCT. The lower rates of relapse observed in patients with myeloid leukemias who receive grafts from donors carrying one or more type B KIR haplotypes [49,50] – or KIR genes such as *KIR2DS1* that characterize such haplotypes [51] – suggest that prospective donor KIR typing for patients with two or more *HLA-A*, *-B*, *-C*, and *-DRB1*-matched donor candidates might identify the candidate with an optimal KIR genotype and gene content. Identification of the components of the type B KIR haplotypes (in donors) that are responsible for the lower relapse rate and superior outcome in myeloid leukemia patients – and elucidation of the associated cellular and molecular mechanisms – represent high-priority research objectives. (The subject of donor selection is reviewed more extensively in Chapter 46.)

Donor or recipient vaccination

Active immunotherapeutic approaches to enhancing GVT based on donor or recipient vaccination are being investigated at many transplant centers. Most of these efforts involve immunization of the HCT recipient, as the safety of immunizing healthy donors against minor H antigens or non-polymorphic tumor-associated or -specific antigens has, with a few notable exceptions, not yet been established. Immunogens that have been or are being evaluated in clinical trials include whole proteins, specific peptides or peptide mixtures, DNA, and whole cells, including tumor cells and dendritic cells, most of which are genetically or biochemically modified to enhance their immunogenicity; a variety of adjuvants are also being evaluated. The few published trials to date of donor vaccination have investigated administration of purified idiotype protein harvested from multiple myeloma patients to their MHC-matched sibling donors [132,133]. No significant toxicity of vaccination with purified idiotype protein was observed in these trials, and cellular and humoral idiotype-specific responses were detected in the donors and also in the sibling recipients to whom they donated bone marrow and, in one case, lymphocytes.

The majority of current vaccine studies are focused on eliciting, by post-transplant vaccination of HCT recipients, immune responses to tumor-associated antigens that are shared by many patients. Vaccination with synthetic peptides contained within the sequence of the WT1 or BCR-ABL proteins or with PR1 peptide (derived from PR3 or neutrophil elastase) has been extensively evaluated in the non-transplant setting, and to a lesser extent in the HCT setting. CML patients with post-transplant relapse have been safely vaccinated with BCR-ABL fusion peptides, and $CD4^+$ BCR-ABL fusion peptide-specific T-cell responses were subsequently detected in several patients [134]. A PR1 peptide vaccine has been administered to patients with AML, CML, and MDS in the allogeneic HCT and also non-transplant settings, and has been associated with durable complete remissions in several patients [135]. $CD8^+$ responses to vaccination with PR1 peptide, however, have frequently shown both low avidity and poor durability. A murine monoclonal antibody recognizing the PR1/HLA-A*02:01 complex has been developed, and has been used to demonstrate that this complex is unequivocally present on the surface of normal hematopoietic stem cells, myeloblasts, and monocytes [136]. Expression of this antigen on the surface of normal, non-transformed cells may in part explain why PR1 peptide vaccination often fails to generate high-avidity HLA-A*02:01-restricted PR1-specific $CD8^+$ T-cell responses in HLA-A*$02:01^+$ individuals.

Several patient-specific cellular vaccines comprising irradiated autologous tumor cells without or with other components have been administered to HCT recipients and shown to be both safe and immunogenic. A vaccine consisting of irradiated autologous leukemic blasts admixed with skin fibroblasts transduced with the *IL2* and *CD40LG* (CD40 ligand) genes was administered post-transplant to nine patients who underwent allogeneic HCT for acute leukemia [137]. Vaccination with the recipient cells did not trigger GVHD, and cellular and humoral leukemia-specific immune responses were detected in several recipients after vaccination. In another trial, a cellular vaccine composed of irradiated autologous leukemic blasts transduced with the *CSF2* (*GMCSF*) gene was administered early after transplant to patients with high-risk AML and MDS [138]. No unexpected toxicity of vaccination or aggravation of GVHD was observed, and several patients showed evidence of vaccine-induced immune responses. Although both of these vaccines were tested in single-arm, early-stage trials that were not designed to provide definitive assessment of vaccine contribution to GVL activity, the outcome of patients treated on both trials when compared with historical controls was encouraging. Further evaluation of these promising approaches to enhancing tumor-specific immunity after allogeneic HCT, therefore, appears to be warranted.

Adoptive cellular therapy – donor lymphocytes

The remarkable potency of DLI for the treatment of recurrent CML after HCT, and its frequent serious toxicities – most notably GVHD and myelosuppression [9,139,140] – have generated intense interest in the development of more selective adoptive cellular therapies that have greater antitumor efficacy, against a wider range of malignancies, with less toxicity to normal, non-malignant tissues. Strategies for exploiting GVT that are based on the adoptive transfer of donor-derived cells permit ex vivo selection and manipulation of the cellular product, and potentially of the donor from whom it is derived, prior to infusion, in addition to independent manipulation of the recipient in order to increase the safety and the efficacy of adoptive therapy. Adoptive transfer approaches also allow the genetic modification and marking of cells prior to infusion to enhance their antitumor potency, improve their safety, and facilitate precise monitoring of their in vivo persistence and trafficking after infusion.

Administration of DLI in escalating doses and selective depletion of $CD8^+$ cells from donor lymphocyte products prior to infusion have been performed in an attempt to harness the antileukemic effect of DLI while minimizing toxicity attributable to GVHD. Sequential administration of escalating doses of $CD3^+$ donor lymphocytes has proven to be an effective approach to the treatment of recurrent CML post-transplant [141,142]. Doses in the range of $1–2 \times 10^7$ $CD3^+$ cells/kg of recipient weight have been associated with high response rates and low rates of clinically significant GVHD. Patients who do not respond to an initial dose at this level often respond to subsequent higher doses, at which the risk of GVHD is greater. Based on the hypothesis that the therapeutic efficacy of DLI for CML is attributable to the activity of $CD4^+$ T cells, and that the GVHD associated with DLI is attributable to the activity of infused $CD8^+$ T cells, donor lymphocyte products selectively depleted of $CD8^+$ T cells have been used to treat recurrent CML and multiple myeloma post-transplant [39,40]. Complete responses were observed in a majority of the CML patients and many myeloma patients, with rates of GVHD that were lower than would be expected based on historical controls. Whether the lower rates of GVHD were attributable to the depletion of GVHD-causing $CD8^+$ T cells from the DLI products administered in these studies, or simply due to a lower mean dose of cells administered, cannot be determined from the available data.

A variety of strategies have been explored to enhance the antitumor activity of conventional DLI, with modest success. Administration of individual cytokines such as IL-2 or interferon-α (IFN-α did not consistently enhance the efficacy of DLI, but IFN-α combined with GM-CSF and DLI produced clinical responses in several patients who were refractory to DLI or to DLI and IFN-α) [143]. Surprisingly, however, IFN-α was associated with durable tumor regression in several patients who had persistence of metastatic RCC after reduced-intensity allogeneic HCT and DLI [93,144]. Whether the effect of IFN-α in this setting was attributable to a primary effect on activation or expansion of donor-derived effector cells in the host, or alternatively to a direct antitumor effect on recipient tumor cells, is unknown. Infusion of donor lymphocytes activated and expanded ex vivo via CD3/CD28 costimulation was used in combination with chemotherapy and conventional DLI to treat patients with a variety of aggressive malignancies whose tumors recurred or persisted post-transplant, and complete remissions were seen in eight of 18 patients [145]. Depletion of $CD4^+CD25^+$ presumptive regulatory T cells from DLI products, without or with lymphodepleting chemotherapy prior to infusion, was investigated in a pilot trial [146]. Durable GVL activity accompanied by GVHD was observed in several patients who had not responded to unmodified DLI.

The promising antitumor activity of immune checkpoint inhibitors such as ipilimumab in patients with solid tumors has suggested that these agents might be given in combination with DLI to enhance its antitumor efficacy. The safety and efficacy of a single dose of ipilimumab given as monotherapy for the treatment of post-transplant relapse has already been tested in a pilot study with 29 patients [147]. No aggravation of GVHD was seen, although organ-specific immune adverse events were noted in four patients, and three objective clinical responses (two complete, one partial response) were observed. These results suggest that ipilimumab could be combined with DLI without prohibitive toxicity. Interruption of signaling through the PD-1/PD-L1 axis with blocking monoclonal antibodies was associated with durable regression of several different types of advanced solid tumors in recent trials [148,149], and it is conceivable that interruption of PD-1/PD-L1 signaling with these agents might likewise enhance the antitumor efficacy of DLI.

Ex vivo genetic modification of donor lymphocytes with inducible suicide genes can dramatically improve the safety of DLI, by allowing in vivo ablation of adoptively transferred lymphocytes in the event that they cause GVHD or other toxicity. This approach was pioneered by a transplant group in Milan, Italy [150], who transferred donor lymphocytes transduced with a construct containing the herpes simplex virus thymidine kinase (HSV-TK) gene to recipients of T-cell-depleted grafts from haploidentical related donors. The approach was subsequently extended to the MHC-identical, T-cell-replete transplant setting [151]. The antitumor efficacy of suicide gene-transduced DLI was greater in the T-cell-depleted compared with the T-replete settings due to the immunogenicity of the transgenes, which elicit $CD8^+$ transgene-specific T-cell responses that dramatically limit the in vivo persistence of adoptively transferred, transgene-bearing cells in T-replete HCT recipients [150–152]. Although T-cell responses to transgene products have also been detected after transfer of transduced cells to recipients of T-cell-depleted HCT, GVT activity attributable to adoptively transferred cells has been observed in the majority of recipients [152]. Tumor regression was temporally correlated with the development of GVHD in most responding patients, and GVHD was largely controlled by the subsequent administration of ganciclovir. A novel suicide gene based on fusion of the human caspase 9 death domain to a modified FK506-binding protein (FKBP) domain, which can be activated by an otherwise inert drug that dimerizes the FKBP domain [153], has also been tested in the haploidentical related transplant setting [154]. Donor T cells transduced with the inducible suicide gene increased in frequency after infusion, suggesting limited immunogenicity, and were rapidly ablated with a single dose of dimerizing drug given when GVHD developed.

Adoptive cell therapy with manipulated donor lymphocytes

The low frequency of T cells in unselected donor lymphocyte products that are reactive with recipient tumor cells, combined with the presence in such products of alloreactive cells that contribute to GVHD, has stimulated interest in adoptive therapy with products manipulated ex vivo to expand selectively the subsets of tumor-reactive effector cells. Infusion of donor-derived CTL lines generated by repetitive in vitro stimulation of donor PBMC with recipient CML cells, in one of the first examples of this concept, was followed by complete remission in a CML patient with post-transplant recurrence of accelerated phase disease who had not responded to unselected DLI [155]. Although the contribution of the ex vivo-manipulated cells to elimination of residual leukemia could not be unambiguously established in this case, it did serve to highlight the many potential advantages of adoptive therapy with products enriched for tumor-reactive cells when compared with infusion of unselected donor lymphocytes.

The past decade has witnessed enormous progress in the preclinical development and clinical evaluation of adoptive cell transfer strategies for enhancing GVL activity. A wide range of cell products, in almost all cases donor derived, have been investigated, including homogeneous populations of $CD8^+$ and $CD4^+$ T cell lines or clones that are natively specific for antigens selectively or exclusively expressed on recipient tumor cells, purified natural killer cells, and donor T-lymphocytes that have been genetically modified to render them specifically reactive with molecules or antigens expressed on recipient tumor cells. Key to the successful development and evaluation of these adoptive transfer strategies has been the simultaneous development and continuing optimization of platforms for rapid ex vivo expansion of tumor-reactive cells in cGMP-compliant systems to the numbers required for clinical application. Other technical advances that have profoundly accelerated the development of adoptive cell therapy have included improvements in gene transfer techniques and transgene design.

Adoptive therapy with donor T cells that are natively reactive with antigens expressed by recipient tumor cells, including minor H antigens, non-polymorphic tumor-associated antigens, and viral antigens, has been extensively investigated in recent years. Donor-derived $CD8^+$ cytotoxic T-cell clones specific for tissue-restricted minor H antigens expressed in recipient hematopoietic cells but not recipient fibroblasts were administered to seven patients with relapse of acute leukemia or high-grade MDS after HCT from MHC-matched related donors [156]. Although five patients achieved transient complete remissions after therapy, the in vivo persistence of adoptively transferred cells was limited, and pulmonary toxicity of CTL infusion was seen in three patients. A pilot trial of adoptive therapy with donor-derived T cell lines recognizing the hematopoietic-specific HA-1 minor H antigen to treat relapse in patients with HA-1-expressing leukemias showed minimal toxicity and no GVHD but also little, if any, clinical benefit, and the persistence of transferred cells was again limited [157]. $CD8^+$ T-cell lines reactive with peptides derived from PR3, WT1, or the BCR-ABL junctional sequence were administered prophylactically to 14 CML patients after T-cell-depleted HCT without causing GVHD or other toxicity [158], and seven of the patients achieved durable molecular remission. WT1-specific $CD8^+$ T-cell clones were also given to 11 patients in another trial to prevent or treat relapse of acute leukemia or MDS. Although pulmonary toxicity of unclear etiology occurred in one patient, therapy was otherwise well tolerated. Persistence of adoptively transferred cells was fairly prolonged in some patients, and was correlated with antitumor activity [159]. T-cell lines specific for Epstein–Barr virus (EBV) antigens or the cancer-testis antigen MAGE-A4 have been used to prevent or treat post-transplant relapse of EBV+ [160,161] and EBV− [162] lymphomas, respectively, with potent antitumor activity and durable complete remissions noted in several patients.

Significant improvements in transgene design and in techniques for transferring genes into primary T-lymphocytes to redirect their specificity are actively transforming the field of adoptive cellular therapy by obviating, in most cases, the need to isolate the (usually rare] donor T cells that are natively specific for the desired target antigen. These advances have made it possible to render polyclonal donor T cells, regardless of their native antigenic specificity, capable of recognizing tumor-associated or -specific antigens through the introduction of genes encoding the α- and β-chains of T-cell receptors (TCRs) specific for tumor peptides presented by MHC molecules, or chimeric antigen receptors (CARs) [163] comprising the antigen-binding domains of immunoglobulins typically fused to cytoplasmic signaling domains from the TCR–CD3 complex and one or more costimulatory domains (for a review, see [164]). T cells expressing transgenic TCRs retain the MHC restriction of the T cell from which the receptor was derived, whereas CAR-transduced cells demonstrate MHC-unrestricted cytotoxicity against cells expressing the target antigen – generally a transmembrane molecule with an extracellular domain for which the immunoglobulin moiety of the CAR is specific. TCR- and CAR-transduced donor T cells can be expanded ex vivo with retention of transgenic receptor expression and antigenic specificity, for use in adoptive therapy. Because unselected polyclonal donor lymphocyte populations could contain T cells whose native specificity might include minor H antigens expressed on recipient cells, current strategies for generating TCR- or CAR-transduced donor T cells for use after allogeneic HCT entail isolation of donor T cells specific for common viral pathogens, often herpes viruses such as EBV or cytomegalovirus (CMV), followed by genetic modification with the desired TCR or CAR transgenes. Genetic modification of T cells that are natively virus specific – which are generally far more common in the blood of healthy donors than tumor-specific T cells – should, in principle, create a population of effector cells with potent and specific antitumor activity, by virtue of their transgenic TCRs or CARs, which will not cause GVHD after adoptive transfer, because their native TCRs are specific for viral antigens. Adoptive cellular therapy with ex vivo-expanded TCR- or CAR-transduced T cells has already been extensively tested in the autologous setting, and donor-derived CD19-specific CAR-transduced T cells have been administered to one patient with progressive CLL after allogeneic HCT who subsequently experienced dramatic disease regression [165]. A promising alternative approach to minimizing the risk of GVHD and other potential toxicities associated with adoptive transfer of polyclonal TCR- or CAR-transduced donor T cells is based on the use of zinc finger nucleases to disrupt the endogenous TCR α- and β-chain loci in the T cells [166], which completely abrogates surface expression of their natively encoded TCRs without impairing the specificity or function of the transgenic receptor.

Adoptive therapy with regulatory T cells

Procedures for ex vivo enrichment and expansion of $CD4^+CD25^+$ regulatory T cells that can suppress the in vitro activity or function of effector $CD8^+$ or $CD4^+$ T cells or of NK cells have been described, and there is compelling evidence that these cells can regulate immune responses in vivo (for a review, see [167], and also Chapter 12). The role of such cells in GVHD and GVT after allogeneic HCT in humans remains poorly defined. Studies in murine systems, however, have suggested that adoptive transfer of $CD4^+CD25^+$ regulatory T cells can inhibit GVHD after MHC-mismatched HCT [168–170] without impairing GVT [171]. These studies have suggested that analogous strategies based on adoptive transfer of T cells with regulatory function to preserve GVT while inhibiting GVHD in human HCT could be developed. A pilot clinical trial of adoptive therapy with regulatory T cells expanded ex vivo from umbilical cord blood demonstrated that infusion of the cells was safe and well tolerated [172], suggesting that additional trials to assess the potential of this therapy for preventing GVHD while preserving GVHD are warranted.

Strategies for improving the safety and efficacy of adoptive cell therapy

Despite the considerable progress made in the past decade in adoptive cell therapies for enhancing GVT after allogeneic HCT, much work remains to be done. For example, in vivo persistence of adoptively transferred GVT effector cells will likely be required for optimal antitumor efficacy, but persistence of adoptively transferred cells in many studies has been limited. Several different strategies for improving persistence and establishing durable antitumor immunity, including lymphodepletion of the recipient before adoptive transfer, concurrent administration of T-cell cytokines, and genetic modification of cells for enhanced persistence, are currently being explored. Many recent studies also suggest that the intrinsic differentiation state of adoptively transferred T cells, regardless of whether they are natively tumor reactive or have been rendered so by genetic modification, is an important determinant of the success of adoptive therapy. A growing body of evidence suggests that the differentiation state of $CD8^+$ T cells is inversely correlated with their capacity for proliferation and persistence after adoptive transfer. Improved understanding of the relationship between differentiation state and in vivo persistence and function will likely provide valuable insight into the requirements for establishing sustained GVT activity via adoptive transfer. Genetic modification of cells for adoptive therapy to confer resistance to immune suppressive agents commonly used in the allogeneic HCT setting, such as corticosteroids and mycophenolate mofetil, is also an important and active area of investigation, and such studies, if successful, will facilitate the use of adoptive cell therapy in patients suffering from or at risk for GVHD. Further development of T-cell-depleted transplant platforms in which alloreactive donor T cells are selectively removed from the hematopoietic cell graft prior to infusion will likewise facilitate the development of adoptive therapy in transplant settings where there is a high prevalence of GVHD with unmodified, T-replete grafts. It is anticipated that the development of T-cell-depletion strategies for selectively removing alloreactive donor cells that might potentially contribute to GVHD will alleviate, if not completely eliminate, the problem of poor immune reconstitution observed in recipients of non-selectively T-depleted grafts.

Conclusion

The GVT effect associated with allogeneic HCT is the clearest example of effective immunotherapy in humans. Genetic disparity between donor and recipient is the key to the therapeutic efficacy of HCT, but is also the root of GVHD, its primary limitation. Cellular and molecular dissection of GVT responses has demonstrated that GVT after MHC-matched HCT is likely initiated by donor $CD8^+$ and $CD4^+$ T cells that recognize recipient minor H antigens encoded by polymorphic genes, and that this alloresponse likely recruits additional effector cells recognizing tumor-specific or tumor-associated antigens encoded by non-polymorphic genes that are over- or aberrantly expressed in recipient tumor cells. Accumulating evidence also suggests that donor NK and B cells also contribute to GVT activity. The GVT response in most HCT recipients is therefore likely to comprise a broadly focused immune response directed at a large number of polymorphic and non-polymorphic target antigens. Selective expression of some GVT target antigens in recipient hematopoietic cells and recipient tumor cells, with limited expression in non-hematopoietic tissues, may allow the development of therapeutic strategies for enhancing GVT activity without inducing or aggravating GVHD. Characterization of the extensive sequence and structural variation in the human genome suggests that there are likely to be a large number of polymorphic protein and peptide sequences at which immunotherapy to augment GVT could potentially be directed. It is likely, however, that the extent to which alloimmunity can be exploited to enhance GVT without aggravating GVHD will be limited. Interventions that enhance specific antitumor immunity rather than alloimmunity after allogeneic HCT will therefore have the greatest impact on the outcome of allogeneic HCT.

CHAPTER 17

Dendritic Cells in Hematopoietic Cell Transplantation

Miriam Merad[1] **and Edgar G. Engleman**[2]

[1] Mount Sinai School of Medicine, New York, NY, USA
[2] Stanford University School of Medicine and Stanford Blood Center, Stanford, CA, USA

Introduction: the dendritic cell network

Dendritic cells (DCs) are hematopoietic cells that belong to the antigen-presenting cell (APC) family, which also includes B cells and macrophages. The two main DC subsets are conventional dendritic cells (DCs) and plasmacytoid dendritic cells (PDCs). Although Langerhans cells (LCs) in the skin were described in 1868, their role as APCs was not appreciated until 1973, when Steinman and Cohn identified DCs in mouse spleen as potent stimulators of the primary immune response (reviewed in [1]). Shortly thereafter, several groups reported the presence of DCs in non-lymphoid tissues of rodents and humans, and demonstrated early evidence that these cells contribute to heart and kidney transplant rejection (reviewed in [2]). However, the low number of DCs in vivo, the paucity of markers that distinguish them from monocytes/macrophages, and the problems involved in purifying these cells made for slow progress in the understanding of DC biology. In the 1990s, the development of methods to isolate DCs from blood [3,4] and to generate DC-like cells from bone marrow (BM) or monocytes in vitro [5] led to an explosive growth of the DC field. Forty years after their discovery, the DC's exquisite ability to mount adaptive immune responses to foreign antigens is undisputable, and their contribution to the induction of tolerance to self-antigens is also becoming increasingly evident. Consequently, the potential therapeutic benefits of modulating DCs for vaccines and suppressive therapies against pathogens, tumors, and/or autoimmune diseases are now being pursued in both the academic and industrial worlds. In recognition of the importance of the discovery of the DC system, Ralph Steinman was awarded several prestigious prizes, including the Gairdner Award in 2003, the Lasker Award in 2007, and the Nobel Prize in Physiology or Medicine in 2011 [6]

Classical or conventional DCs (DCs) (Figure 17.1)

Classical DCs refer to all DCs other than PDCs. DCs form a small subset of tissue hematopoietic cells that populate most lymphoid and non-lymphoid tissues. DCs have an enhanced ability to sense tissue injuries, capture environmental and cell-associated antigens, and process extracellular antigens into major histocompatibility complex (MHC) I and MHC II peptides [7–9]. DCs also have a unique ability to migrate loaded with tissue antigens to the T-cell zone of lymph nodes in the steady state and inflamed state [10] and to prime naïve T-cell responses [11]. DCs constitutively express on the cell surface the hematopoietic markers CD45, MHC II, and CD11c and lack T-cell, natural killer (NK)-cell, B- ell, granulocyte, and erythrocyte lineage markers. This definition, however, is much too limited and should not be used in isolation to define DCs, especially in non-lymphoid tissues. Indeed, CD11c expression is evident on several macrophage populations – particularly lung and intestinal macrophages – but also on DC precursors and other leukocytes. Additional markers have now been shown to facilitate the delineation of DCs and macrophages. For example, expression of the tyrosine kinase receptor fms-like tyrosine kinase 3 (Flt3), also called fetal liver kinase 2 (Flk2) or CD135, is an excellent marker with which to distinguish DCs from macrophages.

DCs in non-lymphoid tissues (Figures 17.2 and 17.3)

DCs represent 1–5% of tissue cells depending on the organ and include two major subsets, the CD103$^+$CD11b$^-$ and the CD11b$^+$ DC subsets.

The CD103$^+$CD11b$^-$DC subset

The CD103$^+$CD11b$^-$ DC subset (referred to here as CD103$^+$ DCs) shares its origin and function including a superior ability to cross-present cell-associated antigens with lymphoid tissue CD8$^+$ DCs [12,13]. CD103$^+$ DCs populate most connective tissues. The proportion of CD103$^+$ DCs among total DCs rarely exceeds 20%. In the intestine, CD103$^+$CD11b$^-$ DCs are enriched in the Peyer's patches, and coexpress the marker CD8 on the cell surface, express low levels of MHC II and represent lymphoid tissue-resident CD8$^+$ DCs, whereas most lamina propria CD103$^+$ DCs express CD11b and are discussed in the CD11b$^+$ DC section below [14,15]. CD103$^+$ DCs lack the macrophage markers CD11b, CD115, CD172a, F4/80, and CX$_3$CR1. They express higher Flt3 levels than CD11b$^+$ DCs, proliferate in response to Flt3L and are markedly reduced in Flt3L$^{-/-}$ mice [16]. CD103$^+$ DCs commonly express the C-type lectin receptor langerin, except for intestinal and pancreatic CD103$^+$ DCs [16,17]. CD103 expression is dependent on the tissue environment and is regulated by local production of the cytokine Csf-2 [18–21].

The CD11b$^+$ DC subset

The CD11b$^+$ DC subset is a heterogeneous population of tissue antigen-presenting cells and consists of a mixture of tissue DCs and macrophages, providing a major source of confusion on the exact contribution of DCs and macrophages to tissue immunity. CD11b$^+$ DCs most often lack the integrin CD103 and express the integrin CD11b. In the muscle and lamina propria, CD11b$^+$ DCs arise from DC-restricted precursors and monocytes, but markers that distinguish the two ontogenically distinct subsets differ between tissues.

For instance, in the muscle, expression of FcgRI helps distinguish between these two subpopulations [22], whereas expression of CD103 helps distinguishes between the two CD11b$^+$ DC subsets in the lamina propria [14,23].

Epidermal Langerhans cells (LCs)

Epidermal LCs are the DCs that populate the epidermal layer of the skin [17]. LCs account for 3–5% of epidermal cells, with approximately 700 LCs/mm^2 [17]. LCs stand apart from other tissue DCs through their unique ontogeny and homeostatic properties [24]. Phenotypically, LCs express lower MHC II, intermediate CD11c levels, and very high levels of the C-type lectinlangerin (CD207) compared with dermal DCs. Langerin is involved in the formation of the intracytoplasmic Birbeck granules, which for a long time represented a conspicuous but pathognomonic marker for LCs. Murine LCs are uniformly CD11b$^+$ and F4/80$^+$ and lack CX_3CR1 expression [17]. In contrast to most DCs, LCs develop independently of Flt3 and Flt3L [16], but require Csf-1 and Csf-1R for their development [25].

Tissue migratory DCs

Tissue migratory DCs are located in the peripheral lymph nodes (LNs), having migrated to the tissue-draining LNs through the lymphatics, in contrast to the blood-borne lymphoid resident DCs [26]. The nature of migratory DCs depends on the site of LN drainage [27,28].

Figure 17.1 Origin of dendritic cells (DCs) in mice. This cartoon illustrates a hypothetical view of DC differentiation pathways in mice. Embryonic hematopoietic precursors give rise to Langerhans cells (LCs) in the skin. LCs are maintained by radioresistant hematopoietic progenitors that have taken residence in the skin during steady-state conditions. After severe skin injury, local LC progenitors are eliminated and LCs are repopulated by circulating monocytes. Common myeloid precursor (CMP) and common lymphoid precursor (CLP) give rise to DCs, but the DC differentiation potential is restricted to the Flk2 (fms-like tyrosine kinase 2, the receptor for Flt3L)-positive populations in mice and humans. A common DC/plasmacytoid DC precursor (CDP) has been identified in the bone marrow as an Flk2$^+$CD115$^+$MHC II$^+$ cell. This precursor likely derives from Flk2$^+$ CMP and Flk2$^+$ CLP, although this has still not been confirmed. CDPs give rise to PDCs and to DC precursors (DCps) in the blood (MHC II$^+$CD11c$^-$) that can further differentiate in lymphoid organs into CD8$^+$ and CD8$^-$ DCs. Lymphoid organ DCps divide in situ for three or four cycles. In contrast to lymphoid organ DCs, it is still unclear if CDPs participate in DC homeostasis in non-lymphoid tissues. On the other hand, monocytes have been shown to give rise to DCs in non-lymphoid tissue including the gut and the lung, and potentially the dermis, while they do not give rise to splenic DCs in the steady state. However, under inflamed conditions, monocytes can be induced to differentiate into splenic DCs and epidermal LCs. Lymph nodes (LNs) and mucosa-associated lymphoid tissue contain DCs that originate from the blood (i.e. are CDP progeny) in addition to DCs migrating from peripheral non-lymphoid tissue. For example, skin-draining LNs but not the mesenteric LNs contain LC-derived DCs, while both LNs contain CD8$^+$ DCs. MHC, major histocompatibility complex; UV, ultraviolet.

Figure 17.2 Cutaneous dendritic cells (DCs) in mice and humans. (a) Epidermal sheet isolated from C57BL/6 mice and stained for major histocompatibility complex (MHC) class II molecules and langerin. Langerhans cells (LCs) coexpress MHC class II and langerin, and form a very tight network of cells that contrast with dermal DCs, which are more sparsely distributed. (b) Cross-section of murine skin stained with anti-CD11c, antilangerin, and DAPI (which stains nuclei) to reveal LCs and dermal DCs. LCs coexpress CD11c and langerin, whereas dermal DCs express CD11c but not langerin. LCs are present exclusively in the epidermis, but migrating LCs on their way to the LNs can also be found in the dermis. (c) Human epidermal sheet stained with anti-CD1a antibody. Human LCs express CD1a; they represent the major hematopoietic cell population in the epidermis, where they form a tight network of cells constituting the first immunologic barrier with the environment. (d) Epidermal and dermal sheets were isolated from human skin maintained in culture for 2 days to allow the LCs and dermal DCs to migrate into the medium. Migrating cells are stained with Giemsa. Arrows show a contaminating keratinocyte in the epidermis and a contaminating T cell in the dermis. Data source: M. Bogunovic and M. Merad (unpublished material) and M. Collin (unpublished material).

Although most tissue migratory DCs die in LNs, there is evidence that some DCs exit through efferent lymphatics to gain access to the blood and play a role in tissue immune response and tolerance (for a complete review, see [26,29]). Non-lymphoid tissue DCs constantly migrate through afferent lymphatics to the T-cell areas of LNs charged with antigens [26] in the steady state and this process increases manyfold in response to inflammatory signals (reviewed in [26,29,30]). DC migration to the draining LNs is controlled by CCR7 [30,31]. CCR7$^{-/-}$ mice that lack migratory DCs [31] have helped characterize tissue migratory DCs. In the steady state, migratory DCs are distinguished from resident DCs based on higher MHC II expression and low-intermediate expression of CD11c. However, these features become obsolete during the inflamed setting.

Plasmacytoid DCs (PDCs)

PDCs are extensively reviewed in [32]. Similarly to DCs, PDCs express MHC class II molecules constitutively and lack CD3, CD19, CD14, and CD56 lineage markers. Although human PDCs express very low-to-undetectable levels of CD11c, they express CD4 and CD45RA antigens, the c-type lectin receptor BDCA2, and BDCA4, a neuronal receptor often used to identify PDCs in vivo. Human PDCs also express high levels of the interleukin-3 (IL-3) receptor (CD123). Murine PDCs express low levels of the integrin CD11c, express low levels of the lineage markers CD45RA/B220 and ly6C/GR-1 molecules, lack CD11b, and express plasmacytoid DC antigen-1 (PDCA1) and siglec-H, a member of the sialic acid-binding immunoglobulin-like lectin (Siglec) family, recently identified as a specific surface marker of PDCs in mice. In the steady state, PDCs are generated in BM, circulate in the blood, enter LNs through high endothelial venules, and accumulate in the paracortical T-cell-rich areas of LNs. Hence the migration pattern of PDCs closely resembles that of lymphocytes but is clearly distinct from that of DCs. Migration of PDCs into LNs is greatly enhanced when the LNs drain a site of inflammation. PDCs are absent from non-lymphoid peripheral tissue such as the skin in the steady state, but they can be found in these tissues when they are inflamed.

Human DCs

Most of our understanding of human DC heterogeneity stems from studies of skin and blood DCs. However, increased refinement of flow cytometric approaches allowing cross-correlation of a large number of surface markers and the development of novel genomic profiling methods have recently fostered an improved understanding of human DC heterogeneity**.** Human DCs are defined as cells that lack lineage (Lin) markers (CD3, CD19, CD14, CD20, CD56, GPA) and constitutively express MHC II. Human PDCs were initially described as Lin$^-$MHC II$^+$CD11c$^-$CD4$^-$CD123 (IL-3 receptor)$^+$ and referred to as DC2 [33,34]. The term DC2 is not used any longer and PDCs are best characterized as Lin$^-$MHC II$^+$CD303$^+$(BDCA2) CD304$^+$(BDCA4$^+$), whereas human DCs are characterized as Lin$^-$ MHC II$^+$CD11c$^+$ [35–37], although in humans, CD11c is also expressed on the majority of human monocytes and macrophages. In contrast to mice, in which circulating pre-DCs differentiate into mature DC subsets once they reach peripheral tissues, in humans two DC subsets expressing the non-overlapping markers CD1c$^+$ (BDCA1$^+$) or CD141$^+$ (BDCA3$^+$) [38–40] are present in the blood circulation. CD1c$^+$ DCs represent by far the most numerous DC subset in human blood, whereas CD141$^+$ DCs form a minute blood population. Gene chip (meta)analysis of the transcriptome of multiple mouse and human DC subsets and functional studies of these cells revealed that human CD141$^+$ DCs are related to mouse CD8$^+$ DCs, whereas human CD1c$^+$ DCs are more related to mouse CD11b$^+$ DCs [41,42].

In vitro-derived DCs and PDCs

In humans, CD34$^+$ progenitor hematopoietic cells are commonly used to derive LC- and dermal DC-like cells [43]. Monocytes are also a common source of DC-like cells, referred to as monocyte-derived DCs. Granulocyte–macrophage colony-stimulating factor (GM-CSF) is the most common cytokine used to obtain DCs in vitro, although it is dispensable for DC development in mice in the steady state [44]. Transforming growth factor-β is required to obtain LC-like cells in vitro in humans and epidermal LCs in vivo in mice [45]. Murine BM cells can also be used to obtain DC-like cells in the presence of GM-CSF either alone or in combination with tumor necrosis factor [43]. PDCs can be generated from BM cells in cultures enriched with the cytokine fms-like tyrosine kinase ligand-3 [44]. Although in vitro-derived DCs differ from in vivo-generated DCs, these culture systems have been extremely valuable for analyzing the molecular basis of DC function.

DC functions

In contrast to most cell populations, DCs are defined by a set of properties that include both functional and phenotypic properties. The ability to take up, process, and present antigens, to migrate selectively through tissues, and to prime naïve T-cell responses are defining DC properties. The superior ability of DCs, particularly DCs, to stimulate T cells became clear in the late 1970s from studies that compared the ability of DCs, B cells, and macrophages to stimulate a primary mixed lymphocyte reaction, which could be used as a model for graft rejection if T cells were isolated from the donor graft and DCs from the recipient. Normally, mixed lymphocyte reactions are carried out with equal number of stimulator (APCs) and responder (T cells), but only one DC is necessary to activate 100–3000 T cells, consistent with the concept that DCs are specialized to initiate immunity [1]. Elegant studies have subsequently shown that mice deficient in DCs are defective in initiating adaptive T-cell responses [46], whereas mice that genetically lack macrophages (Csf-1$^{op/op}$) are not [47]. Now it is clear that DCs form a specialized system to prime T cells not only to mismatched MHC proteins, but also to minor histocompatibility antigens (mHAs) and foreign proteins.

More recently, several studies have demonstrated that, in addition to inducing immunity, DCs can play a critical role in the induction of central and peripheral tolerance, a function that might prove useful in the setting of allogeneic HCT. Although it seems counterintuitive that potent APCs induce tolerance, it is now clear that induction of tolerance in addition to immunity requires two critical functions that are performed uniquely by DCs [1]. First, the antigen sampling and migratory capacities of DCs effectively allow naïve T cells to come into contact with peripheral antigens that they would otherwise not encounter. Indeed, cell-derived antigens located in diverse anatomic sites in the body must be found and recognized by T cells that circulate in the bloodstream. This task is made more difficult by the low density of specific antigen–MHC complexes on the surface of most cells (<100 molecules per cell), which must be recognized by low-affinity T-cell receptors on T-cell clones with a frequency of 1/10^6 [1]. In addition, most somatic cells lack costimulatory molecules that drive the clonal expansion of T cells, production of cytokines, and development of cytotoxic T cells. DCs provide a means to overcome these challenges. Located in most tissues, DCs capture and process antigens and display large amounts of MHC–peptide complexes on their surface. DCs charged with antigens migrate to the LNs, where they locate in areas that are rich in T cells. The second major property of DCs is their capacity to translate environmental cues to T cells, in a manner that shapes the nature of the T-cell response to such antigens. The capacity of DCs to translate the environment is based on their capacity to respond to environmental stimuli through a maturation process [48].

One of the most complex and intriguing aspects of DCs is the process by which they mature, in situ, as first revealed in studies of LCs. Thus, freshly isolated LCs, which express low levels of MHC class II, are unable to present antigens to naïve T cells. However, upon culture in vitro, LCs increase their expression of MHC class II and T-cell costimulatory molecules, and are able to prime naïve T cells in vitro [1]. Subsequent studies showed that when LCs receive certain inflammatory signals, they can be induced to leave the epidermis and migrate to the draining LNs, where they localize in T-cell areas. These results establish the concept of DCs as immune sentinels, enabling naïve T cells that lack the ability to circulate through tissues to sample peripheral tissue antigens.

More recent studies have also suggested that not only are DCs able to present and initiate an immune response against tissue antigens, but they are also able to instruct T cells to migrate back to the tissue from which they originated, which could be particularly helpful if DCs acquired antigens at sites of infection [49]. Stimuli such as Toll-like receptor (TLR) signals, inflammatory cytokines, T-cell ligands such as CD40 ligands, and disruption of homotypic contacts between immature DCs have been shown to lead to a series of biochemical and phenotypic changes that result in DC maturation (reviewed in [50]). First, there is an increase in macropinocytic uptake, followed by downregulation of endocytic activity. Second, MHC molecules escape from the lysosomal compartment and are transported to the plasma membrane. Finally, the levels of MHC class II, costimulatory molecules, and MHC class I increase at the cell surface and extend into finger-like projections or dendrites, which dramatically enhance DC migration to the draining LNs and the ability of these cells to interact with other cells in their environment. Concomitant with these events, the cells also enhance their ability to form and accumulate peptide–MHC class II complexes, even using antigens internalized before exposure to the maturation stimulus. The end-point of the maturation process leads to functionally competent DCs able to engage naïve T cells.

Most studies of DC maturation have been performed in the context of injury signals, and therefore DC maturation has been wrongly thought to occur only in the context of inflammation. It now appears clear that mature DCs are present in LNs in the steady state, suggesting that maturation can occur independently of inflammatory signals [48]. The immunologic role of DCs in the steady state is becoming a focus of numerous laboratories. There is considerable evidence that DCs function not only to initiate immune responses, but also to maintain peripheral tolerance, by deleting self-reactive T-lymphocytes and/or expanding regulatory T cells amid a constant steady-state flow of mature tissue-derived DCs to the T-cell area of the draining LN [51].

Antigen presentation

Antigen presentation is extensively reviewed in [50]. All DC populations constitutively express high levels of MHC class II molecules dedicated to presenting peptides derived from exogenous antigens. Mechanisms for capture of these antigens can be distinguished on the basis of the size of the cargo internalized and/or the mechanisms of internalization, which include phagocytosis, macropinocytosis, clathrin-dependent receptor-mediated endocytosis, and caveolin-mediated endocytosis. Phagocytosis involves the ingestion of large particles or cells greater than 1μm in diameter. Macropinocytosis is constitutive in DCs and macrophages, and accounts for the uptake of large quantities of extracellular fluid and fluid-dissolved antigens. Receptors such as DEC-205 and FcRγ, upon ligation to their ligands, form complexes that are typically internalized by clathrin-coated vesicles. Proteins internalized by any of these mechanisms eventually reach the endosomal/lysosomal compartments, where they can be processed by resident proteases and loaded onto MHC class II molecules. Classically, the MHC class I pathway provides for the presentation of endogenous cellular antigens. For example, in virally infected cells, viral protein expressed in the cytosol is subject to proteosomal proteolysis, and the resulting peptides are translocated via transporters associated with antigen processing (TAP transporters) into the endoplasmic reticulum lumen and loaded onto MHC class I molecules. Although this process remains true for infected DCs, non-infected DCs can also take up, process, and present viral antigens to $CD8^+$ T cells through a process called cross-presentation. Soluble exogenous antigens can also be cross-presented to $CD8^+$ T cells. It is now clear that although cross-presentation occurs with greatest efficiency in DCs, other cells, such as macrophages and liver sinusoidal endothelial lining cells, also may have this potential. The mechanisms that regulate cross-presentation are currently an active area of research.

Stimulation of allogeneic T cells

Alloreactivity is the response of T cells to MHC complexes or mHAs not encountered during thymic development. The nature of the allogeneic T-cell response differs depending on whether the presenting MHC molecules of the recipient are matched or mismatched with those of the donor. The frequency of T cells specific for foreign antigens is thought to be approximately one in 10^6, whereas the frequency of T cells that recognize allogeneic MHC molecules is thought to be 1000-fold higher (one in 10^3), which results in a very strong primary alloresponse [52]. The molecular basis underlying the specificity of alloreactivity has been a matter of debate, and several studies have suggested that the response of T cells to allogeneic MHC–peptide complexes is less peptide specific than the T-cell response to conventional antigens, and that this “degenerate” response explains the high frequency of alloreactive T cells [52]. A study in mice elegantly demonstrated that the high precursor frequency of alloreactive T cells is due to polyspecificity and not to “degeneracy” as T cells have a germline-encoded capacity to recognize multiple distinct peptide-mismatch MHC molecules [53].

In current clinical transplantation settings, the MHC molecules of donors and recipients are usually matched. In these situations, donor T cells recognize MHC-bound mHA peptides derived from the protein products of polymorphic genes that are present in the recipient but not in the donor [54]. In contrast to solid tumor-associated antigens, all mHAs should theoretically be able to elicit T-cell responses since the donor immune system is not tolerant to these antigens. The clinical manifestations of immune responses against mHAs are likely to be determined by the specific tissue expression of the proteins encoding these antigens. mHAs constitutively expressed in many tissues are likely to be targets for a combined alloreactive immune response directed against the host tissue [graft-versus-host disease (GVHD)] and the tumor [graft-versus-tumor (GVT)], whereas T-cell responses directed against antigens that are restricted to the hematopoietic system, including the malignant hematopoietic cell clone, are likely to mediate GVT reactivity without severe GVHD. Numerous human mHAs have been described and include mHAs derived from autosomal genes such as HA-1, HA-2, HA-3, HA-8, HB-1, and BCL2A1, and those that derive from the H-Y gene [55]. Most mHA-specific T-cell responses identified to date have been directed against mHAs expressed on hematopoietic cells, which favors the possibility that direct presentation by host professional APCs may be a more efficient way to induce tumor-specific $CD8^+$ T cells than is cross-presentation by donor APCs, which requires uptake of exogenous antigens. Detailed genomic typing of the allelic variants of the targeted mHA in the patient and the donor, in addition to examining the expression and functional recognition of the target mHA on the malignant cells, has the potential to lead to novel immunotherapy strategies in clinical transplantation.

Functions of PDCs

One important function of human and mouse PDCs is to produce large amounts of interferon-α (IFN-α) in response to infectious pathogens. In addition to its antimicrobial properties, IFN-α can also promote T helper cell type 1 differentiation and has been shown to contribute to autoimmune disease [56]. The capacity of PDCs to capture and present antigens to T-lymphocytes is still being examined in several settings. Freshly isolated human and mouse PDCs are very poor inducers of T-cell proliferation; however, upon activation, PDCs can differentiate into mature DCs with high levels of MHC class II and costimulatory molecules and T-cell stimulatory activity [46]. More recent studies indicated that PDCs exposed to immune complexes can use their surface Fc receptors to take up the antigens present in these complexes, leading to their processing and presentation to both $CD4^+$ and $CD8^+$ T cells [57]. In humans, freshly isolated PDCs induce anergy in human $CD4^+$ T-cell clones with various antigenic specificities. IL-2 and IFN-γ production by T cells is impaired, whereas IL-10 production is increased. Anergy is reversed by the addition of exogenous IL-2. In the mouse, freshly isolated antigen-pulsed spleen PDCs induce minimal proliferation and no cytokine polarization in antigen-specific T cells. Thus, PDCs, particularly in their immature state, or in certain anatomic localizations, may have tolerogenic functions, although the exact nature and mechanisms of these functions remain to be explored [46]. In allogeneic HCT, donor PDCs are enriched in granulocyte colony-stimulating factor (G-CSF)-mobilized peripheral blood mononuclear cells and are also present in donor leukocyte infusions (DLIs). Therefore, the immunomodulatory properties of PDCs should be examined in this context.

Non-professional APCs

Other cell types in addition to professional APCs can express MHC class II molecules, costimulatory molecules, and accessory factors including MHC invariant chains, HLA-DM and HLA-DO, under normal or pathologic conditions. These cells, sometimes referred to as non-professional APCs, include endothelial cells [58] and some epithelial cells [59]. These cells have a heterogeneous capacity for antigen processing and presentation of peptides that are often derived from endogenous proteins. Tissue inflammatory reactions such as those induced by GVHD may also increase the presentation capacity of non-professional APCs, enhancing local inflammation [60].

DC homeostasis in the steady state

Based on our current understanding of DC homeostasis, there is a continual recruitment of blood-borne DC precursors to peripheral tissue and lymphoid organs that gives rise to immature end-stage differentiated DCs. Peripheral tissue DCs migrate through the afferent lymphatics to draining LNs, where their life is limited to days [61]. Recent studies have led to a reappraisal of the importance of local renewal in DC homeostasis under quiescent conditions. Studies of parabiotic mice showed that, in contrast to other DC populations in the spleen and LNs, LCs were maintained exclusively by local hematopoietic precursors that had taken residence in the skin [62]. Local self-renewal of DCs has now been confirmed, although at much lower levels, in a number of tissues, including spleen, LNs, and dermis [63]. Short-pulse-labeling experiments label approximately 5% of tissue DCs without significant incorporation into monocytes or blood DCs, excluding a contribution from recent blood emigrants to labeling in the tissues [63]. In humans, 2–3% of LCs are in S/M_2 phase by cell cycle analysis, and a similar proportion label with Ki-67 antibodies (M. Bogunovic and M. Merad, unpublished data). Recipient LCs can be identified unequivocally 1 year after human BM transplantation [64], and donor LCs persist in transplanted human limbs [63].

Importantly, in contrast to the steady state, severe skin injuries lead to the elimination of self-renewing LC progenitors followed by the recruitment of blood-borne monocytes and their differentiation into LCs in a *csf-1*-dependent manner [63]. These data are consistent with earlier studies suggesting that, in experimental inflammatory conditions, DCs are clearly derived from classic monocytes [65,66], and establish the concept that DC homeostasis is critically dependent upon conditions of quiescence or inflammation.

Monocyte-derived DCs at sites of inflammation

Several studies have demonstrated that monocytes infiltrate inflamed tissues and differentiate into $CD11c^+$ DCs in vivo [67–69]. More recent experiments have shed light on the mechanisms responsible for DC formation in such sites. These studies have shown that T helper cells, which are often seen in association with monocytes/macrophages in inflamed tissues, can drive DC differentiation from monocytes [70]. For example, in the affected skin of patients with psoriasis, TH1 and TH17 cells interact with monocytes and instruct these cells to differentiate into TH1- and TH17-promoting DCs, respectively. Correspondingly, in acute atopic dermatitis, TH2 cells interact with monocytes and elicit the formation of TH2-promoting DCs. DC formation requires cell contact, whereas TH subset specific cytokines dictate DC function and the expression of DC subset specific surface molecules. Interestingly, the phenotypes of T-cell-induced DC subsets are maintained following subsequent stimulation with a panel of TLR agonists, suggesting that TH-derived signals may outweigh downstream TLR signals in their influence on DC function.

Although these results were obtained in studies of human cells, we recently demonstrated in mice that activated TH1, TH2, and TH17 subsets also promote the differentiation of monocytes into functionally specialized DCs (M. Davidson and E. Engleman, in preparation). Of interest, in the murine system whereas all T helper subsets induce the formation of DCs, TH17 cells uniquely promote the formation of IL-12/IL-23, producing DCs that can polarize both naïve and TH17 cells to a TH1 phenotype. This phenomenon was observed in the inflamed spinal cord of mice with experimental autoimmune encephalomyelitis (EAE), a mouse model of multiple sclerosis, and might be responsible for the well-documented conversion of previously committed TH17 cells into IFNγ-producing TH1 cells within the spinal cord of such mice [71].

These results suggest that TH cells regulate the secondary immune response by instructing monocytes to differentiate into DCs, which in turn trigger naïve CD4$^+$ T cells to acquire similar effector functions as the TH cell subset that initiated DC differentiation. Such an amplification loop would be beneficial during memory responses, but deleterious if uncontrolled during inflammatory diseases. The numerical predominance of TH cells in most chronically inflamed tissues suggests that these cells may be principally responsible for shaping the local DC repertoire. However, this does not exclude the possibility that monocytes also receive signals from other cell types. Thus, NK, CD8$^+$, and NK T cells can also initiate DC differentiation [72–74].

Response of DCs to conditioning therapy

Conditioning

A number of different modalities are used to condition the recipient for HCT. In humans, myeloablative radiotherapy and alkylator-based regimens are still practiced alongside a range of newer reduced-intensity and minimal or non-myeloablative protocols. Conditioning often takes several days, and maintenance of postgrafting immunosuppression is the rule. In murine experiments, radiation at myelosuppressive or lethal doses without postgrafting immunosuppression has been traditionally employed [75]. Reduced-intensity regimens have been developed [76,77], but the majority of murine studies continue to employ single-dose irradiation without immunosuppression.

Effect of conditioning on blood DCs

In common with other leukocytes, peripheral blood DCs are depleted by conditioning therapy. Clinical studies describe a rapid loss of both DCs and PDCs after myeloablative conditioning, which approximates the decline of neutrophils and monocytes [78]. Less is known about blood DC subsets following reduced-intensity conditioning, although the relative preservation of leukocyte counts in some patients suggests that DCs are also less depleted. One report suggests that PDCs are more labile than DCs after reduced-intensity regimens [79], and another study shows that monocyte-derived DCs are more easily isolated after reduced-intensity than high-dose regimens [80]. Alemtuzumab (monoclonal anti-CD52 antibody) is a component of some reduced-intensity regimens and effects a swift reduction in the number of monocytes and blood DCs, which express CD52, unlike their tissue counterparts [81–84]. Patients often have lower pre-transplant DC levels than normal controls, suggesting that BM hypoplasia associated with prior cytotoxic therapy or hematologic disease reduces peripheral DC counts [78].

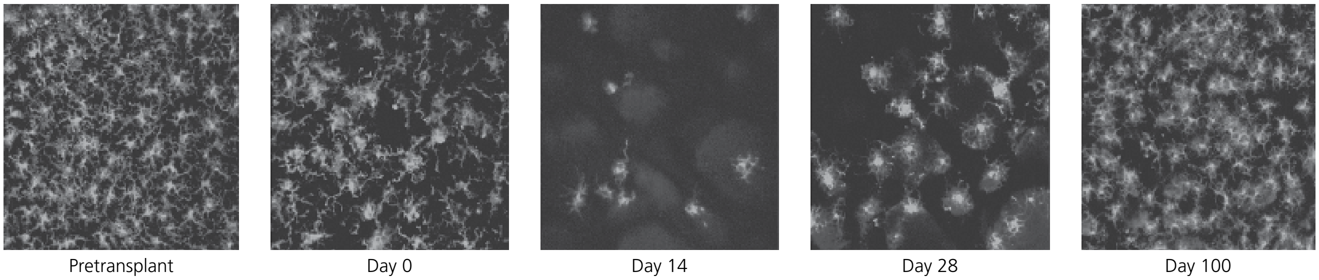
Effect of conditioning on tissue DCs (Figure 17.4)

Surprisingly, in murine models, there are very few data on the immediate effects of radiation conditioning on DCs. We recently found that exposure to ionized radiation leads to increased complement production by recipient DCs yielding C3a and C5a proteins, which in turn controls donor T-cell survival and effector function [85]. Exposure to ionized radiation also leads to rapid loss of recipient DCs from the spleen within 3–5 days; the peripheral blood, LNs, and liver were also reported to be similarly depleted [86]. Most experimental work has utilized chimerism analysis of congenic transplants following stable engraftment to infer the radiosensitivity of various DC populations. In these studies, the spleen and liver DCs are almost completely replaced. In contrast, epidermal LCs [62,87], a component of the dermal DCs [88] and certain macrophage populations, including brain microglia [89] appear relatively radioresistant. LCs recover over several weeks almost exclusively from local host cells [62]; in the brain about 70% of cells are recipient long term [89] and in the dermis approximately 20% [88]. LNs contain some recipient cells depending on the tissue they drain; notably, skin-draining LNs may contain up to 30% recipient LC-derived DCs after transplantation [87]. Other organs such as the gut have not been evaluated in detail and may contain niche populations of resistant cells. The extent of depletion of murine DCs after reduced-intensity conditioning is currently unknown and may be quite different since previous studies on tissue macrophage populations have demonstrated a significant sparing effect simply due to fractionation of irradiation [90].

The analysis of conditioning effects on human tissue DCs has thus far been restricted to the skin. Several studies have documented depletion of epidermal LCs in the first week of transplantation [91–94], and recent data illustrate a greater effect of myeloablative conditioning [64]. An important variable in human transplantation may be the intensity and proximity of prior therapy, since patients often have lower numbers of leukocytes, including DCs, before transplantation than normal controls [64,95].

Mechanisms of conditioning-induced DC depletion

The mechanisms that govern DC depletion by conditioning therapy are poorly understood. Direct cytotoxicity may occur with some agents, although most observers suggest that the secondary release of cytokines, chemokines, and endotoxin is likely to be responsible for the mobilization of DCs from the tissues [96–98]. The role of



Pretransplant Day 0 Day 14 Day 28 Day 100

Figure 17.4 Cutaneous dendritic cell turnover in patients transplanted with allogeneic hematopoietic stem cells. Epidermal sheets isolated from patients at different times after transplant were stained with anti-CD1a. locally derived tumor necrosis factor-α and IL-1β in mobilizing LCs from skin explants is well described [99]. It should not be overlooked that post-transplant aplasia alone, which accounts for severe leukopenia in the peripheral blood, could lead to a significant depletion of DC populations with rapid turnover. The relative contributions of precursor depletion and enhanced mobilization are difficult to resolve in humans, whereas in mice parabiosis and congenic transplantation have allowed a distinction between populations that are more or less dependent on blood-borne precursors [62,100].

Qualitative effects of conditioning on DCs

Conditioning exerts qualitative effects on DCs. Irradiation induces a transient upregulation of costimulatory molecules and IL-12 expression [86]. As with the stimulation of migration, secondary stimulation by cytokines and microbial products is likely to be important. Although this has not been directly shown in the context of transplantation, circumstantial evidence comes from the ability of cytokine and lipopolysaccharide (LPS) antagonists to diminish GVHD [97,101]. Some work also demonstrated DC activation by NK cells and other effectors of innate immunity (reviewed in [102]).

There are no data concerning the activation status of DCs as the intensity of conditioning is reduced, but the general assumption is that both the direct toxicity to organs and the immediate immunologic consequences are ameliorated. It is interesting that although more intensive conditioning should generate an increased inflammatory response, this may be offset to some extent by a greater depletion of recipient cells prior to transplant. Recipient DCs may "go quietly" after reduced-intensity conditioning, but there is also evidence of a high cumulative rate of late GVHD after some regimens, consistent with eventual recognition of a significant burden of recipient DCs [103,104].

Homeostasis after transplant: content of the graft

The recovery of DC populations after allogeneic HSC transplantation is influenced by complex and interacting variables. The donor hematopoietic cell inoculum contains DC precursors and mature DCs [105,106]. Although practically undetectable after infusion, the relative proportions of DC subsets in different grafts have been linked to transplant outcomes. In particular, PDCs are five times more abundant than DCs in G-CSF-mobilized peripheral blood progenitor cells (PBPCs), whereas DCs and PDCs are present in approximately equal numbers in BM [105,106]. In keeping with this, the proportion of T helper cells type 2 in G-CSF-mobilized PBPCs is much higher than in normal peripheral blood or BM [105,106]. These observations have been used to explain the equal incidence of acute GVHD following PBPC and BM transplant even though the total $CD3^+$ cell content of PBPCs is 10-fold higher than that of BM. Among PBPC recipients, a higher frequency of PDCs was associated with increased risk of death from relapse in one report [107], although in general total DC content is correlated with CD34 dose and a positive outcome [108]. The relatively low risk of GVHD after cord blood transplantation has also been linked to the apparently immature or tolerogenic status of cord blood DCs [109].

Numerical recovery of DCs

With the advent of accurate blood DC counting [78], many studies have analyzed the numerical recovery of blood DCs after allogeneic HCT [78,83,108,110–113]. In the first study, expression of DC activation antigens CD83 and CMRF-44 was used to confirm the identity of lineage-negative, MHC class II-positive cells as DCs. Subsequent work has defined DCs as $CD11c^+$ myeloid or $CD123^+$ PDCs of the lineage-negative, MHC class II-positive fraction. Overall, DCs recover faster than PDCs [79], and brisk reconstitution is associated with improved outcomes [111–113]. This is perhaps not surprising given that normal blood DC counts are promoted by good BM function and the absence of GVHD. DC recovery is apparently not related to the dose of CD34 cells in the graft itself [108].

From earlier work on the skin, it was apparent that LC numbers were reduced for several months post-transplant, although separation of conditioning from later effects was not clear [91–94]. Accurate blood DC counting has since revealed a profound depression of DC counts in association with GVHD [78,79,81,110,113]. In one study, temporal resolution was sufficient to reveal a transient increase in all blood DC subsets just at the onset of acute GVHD, and to demonstrate that treatment with corticosteroids was a major factor in DC depletion during GVHD [111]. A recent study has shown that activation antigens are expressed just prior to acute GVHD such that twice-weekly monitoring can be used to predict GVHD [114]. The mechanism of DC activation is not known, but activated DCs may be the source of IL-12, serum levels of which also have predictive value [115].

Blood DC chimerism

Several studies focusing on the chimerism of human blood DCs have shown rapid repopulation by donor cells, in parallel with blood myeloid engraftment. In all of these studies, a minority of patients had a small percentage of persistent recipient blood DCs [116–119]. Despite the large number of patients reported in the last two studies, no significant correlations have been observed between DC engraftment and conditioning, donor type, or GVHD. This is perhaps related to the robust conditioning regimens used by most investigators. Also, the potential of the studies to discriminate was limited by sampling different subgroups of patients relatively late, at 6 and 12 months post-transplantation. Taking all the data together, mixed DC chimerism appears slightly more frequent after reduced-intensity conditioning, although to date there have been no analyses of DC chimerism following true "non-myeloablative" or "minimal" conditioning [103,104]. Surprisingly, no clear relationship between GVHD and DC engraftment has been demonstrated, although prior studies on total myeloid engraftment predicted that acute GVHD would favor complete donor chimerism in all peripheral blood leukocytes [120,121]. One study of monocyte-derived DCs showed a positive relationship between donor engraftment, GVHD, and protection from relapse, but whether this simply reflects overall myeloid chimerism is unclear [80]. Although laborious, prospective studies of homogeneous patient groups with frequent and strict chronologic assessment will be required to clarify this in detail.

Peripheral tissue DC chimerism (Figure 17.5)

In animal models, there exists a wealth of data on peripheral DC chimerism of the tissues following BM transplantation. Two factors play a role in determining donor chimerism of DCs in the tissues: the radiosensitivity or extent of depletion by conditioning, and the alloreactivity of donor T cells in the graft. Thus, in congenic transplantation, a number of tissues, such as the epidermis, dermis, and cutaneously draining LNs, retain host DCs as described above

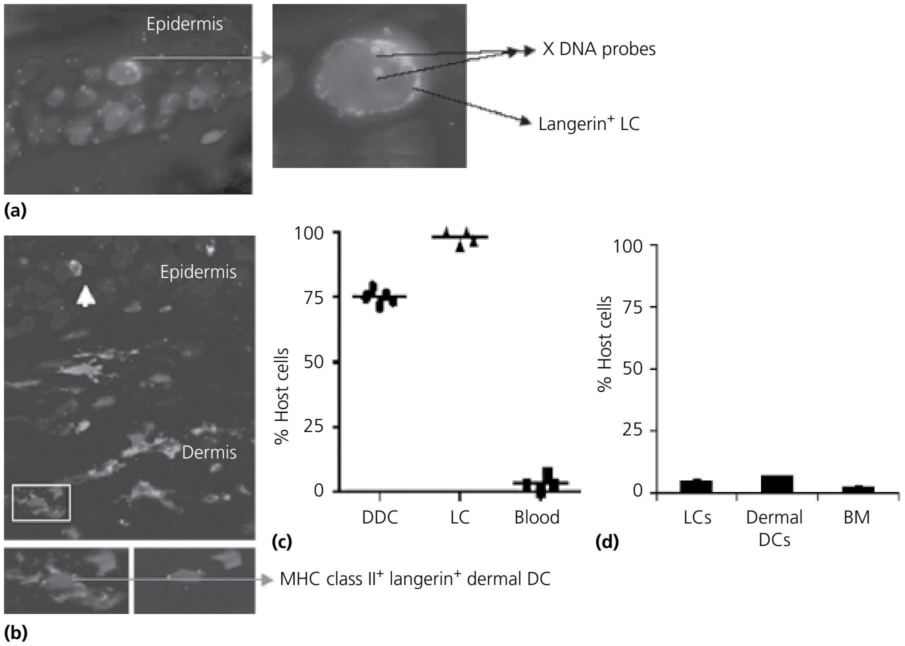

Figure 17.5 Fate of cutaneous dendritic cells (DCs) in patients after sex-mismatched allo-hematopoietic stem cell (HSC) transplant. (a–c) Persistence of human host cutaneous DCs despite complete donor-derived blood chimerism. Non-inflamed skin samples were obtained from patients who underwent reduced intensity for sex-mismatched allo-HSC transplant prior to the development of graft-versus-host disease (GVHD). Cross-sections of 2mm skin biopsies were subjected to fluorescence in situ hybridization of X (Cy3) and Y (Cy2) DNA probes followed by immunostaining of langerin (Cy3) and HLA-DR (Cy5). Nuclei were counterstained with DAPI. One representative image obtained from a female recipient transplanted with male donor hematopoietic cells. (a, b) Overlaid images of three of four color channels in indicated combinations show persistence of host female XX$^+$langerin$^+$ Langerhans cells (LCs) in the epidermis (a) and HLA-DR$^+$langerin$^-$ DCs in the dermis (b). Magnification: ×600. (c) Dot graphs show the percentage of remaining host langerin$^+$ LCs among total the LCs, and HLA-DR$^+$langerin$^-$ cells among the total dermal DCs (DDCs), and the percentage of remaining host leukocytes among the total bone marrow (BM) leukocytes, in each patient 30 days after transplantation. (d) Absence of residual host DCs in advanced cutaneous GVHD lesions. GVHD-affected skin samples were isolated from four patients who underwent myeloablative conditioning for allo-HSC transplant and developed GVHD. The dot graph shows the percentage of remaining host LCs, host dermal DCs, and host BM nucleated cells in five separate patients. Data source: M. Merad and M. Bogunovic (unpublished material).

[62,88]. In addition, several studies showed significant retention of host-derived macrophages in the brain, lungs, and liver [89,90]. However, the situation is radically different when host-reactive donor T cells are introduced in allogeneic transplantation. The effect of donor T cells is generally illustrated by experiments in which mixed myeloid chimeras are converted to complete donor chimerism by lymphocyte infusion [77]. The case for isolated persistent recipient DCs is most clearly demonstrated by the conversion of LCs to donor type by donor T cells [87]. Under these conditions, self-renewing local progenitors of LCs are depleted from the skin and replaced by inflammatory monocytes [122]. The fact that skin is a target organ of GVHD may be critical in this process, and it is perhaps less likely that donor T cells can also eliminate APCs in non-inflamed organs such as the brain.

DC chimerism in the tissues is more difficult to examine in humans, and for this reason all studies of human transplant recipients completed to date have been confined to the skin. An important early paper described the persistence of recipient LCs for up to 120 days after conventional transplantation, using quinacrine to identify the Y body of male CD1a$^+$ (OKT6$^+$) cells [123]. An interim report showed no clear engraftment of LCs with time, which may have reflected technical difficulties with combined immunofluorescence and fluorescence in situ hybridization prior to confocal microscopy [124]. More recent studies using emigrated LCs found that engraftment is largely complete by 100 days, although engraftment occurs more slowly after reduced-intensity conditioning [64,95]. The effect of prior GVHD in promoting LC engraftment is just discernible at 100 days, and patients without GVHD often harbor a small percentage of recipient LCs for at least 1 year after transplant [64]. Murine data also show persistence of recipient dermal DCs, especially after reduced conditioning [88]. It will be difficult to ascertain in humans whether other interstitial DCs, such as splenic or hepatic DCs, behave similarly to LCs or dermal DCs. Extrapolation from murine studies suggests that LCs have a unique mechanism of homeostasis and that other tissue DCs should turn over even more rapidly in parallel with the blood myeloid compartment. Given this assumption, the protracted survival of recipient tissue DCs appears unlikely in most human transplant recipients. Several factors may promote more rapid donor DC engraftment in humans than mice, including greater mHA disparity and higher T-cell content of the grafts. Prior cytotoxic therapy, which attenuates DC populations pre-transplantation, may also lead to a more rapid depletion of recipient cells. Data are also lacking on DC turnover after minimally intensive transplants, which show gradual engraftment [103] and significantly delayed GVHD compared with more intensive regimens [104]. A notable exception to the relatively rapid turnover of human tissue APCs is the long-term survival of recipient microglia. Their persistence may be of questionable relevance to transplantation immunology, but a post mortem study has shown that more than 98% of recipient microglia survive up to 6 years after transplantation [125].

Acute GVHD

Early work

Acute GVHD is primarily a cell-mediated disorder. The interaction between donor T cells of the inoculum and BM-derived elements of the host lymphoid system was first demonstrated by the elegant experiments of Sprent and colleagues (reviewed in [126]). In these studies, recipient mice were infused with T cells that were later collected from the efferent lymph by cannulation of the thoracic duct, a process known as blood–lymph filtering. Alloreactive T cells are initially trapped in the lymphoid organs for 24–48 hours and then emerge primed to induce GVHD in secondary recipients. Filtering governs the responses of both mHA-reactive T cells, thus demonstrated to be H-2 "restricted" [127], and T cells primed across H-2 differences [128]. By transplanting recipients with donor BM 6 months beforehand, so that recipient DCs are replaced by donor cells at the time of T-cell infusion, it is possible to show that CD4 and CD8 T-cell priming is attenuated, although not completely abolished, and is therefore largely dependent on recipient BM-derived APCs [129].

More recent studies

Blood–lymph filtering experiments heralded a series of tandem transplant studies that defined in detail the roles of recipient and donor DCs [130–132]. Using MHC class I-deficient BM grafts (from β_2-microglobulin knockout mice) to prepare recipient animals, the seminal study of Shlomchik et al. proved that recipient APCs are required for the efficient induction of CD8 T-cell-mediated GVHD across an mHA mismatch [130]. The interpretation of this result is that recipient APCs present their endogenous mHAs in association with class I MHC much more effectively than donor APCs, which must cross-present the same antigen acquired exogenously. Complementary studies in which modified donor cells lack functional antigen-presenting capacity showed that donor DCs do in fact amplify CD8 T-cell-dependent acute GVHD but cannot induce it [131]. It is important to note that $CD4^+$ T cells were absent in these experiments. Although this proves that $CD8^+$ T cells alone can mediate acute GVHD, donor APCs may be licensed much more efficiently to cross-present antigen in a full allogeneic response involving $CD4^+$ and $CD8^+$ T cells [133]. Another model has been used to demonstrate that donor DCs may also participate in the induction of acute GVHD indirectly by elaboration of IL-15 [134].

The contribution of recipient APCs to $CD4^+$ T-cell-mediated GVHD is less clear than in CD8 T-cell-mediated GVHD, partly because of the dual functions of $CD4^+$ T cells in GVHD: help for CD8-mediated cytotoxicity and direct cytokine-mediated organ damage. In turn, the removal of $CD8^+$ T and NK cells from an experimental system reduces IFN-γ-induced MHC class II expression by non-professional APCs and may artificially augment the role of professional APCs when $CD4^+$ T cells are put to the test [102]. The potential for direct CD4 T-cell-mediated pathology was clearly illustrated in one study in which a single MHC class II allele mutation (equivalent to a single mHA) expressed on recipient APCs alone was sufficient to induce lethal GVHD [132]. This finding, however, contrasts with the results of an earlier study in a multiple mHA-mismatched model, which demonstrated a strict requirement for alloantigen on target tissues, not only APCs [135]. Shlomchik and colleagues addressed the role of recipient and donor APCs also in a minor histocompatibility antigen-mismatched model, by using BM grafts or recipients deficient in costimulatory molecule expression [136]. In these experiments, both recipient and donor APCs were sufficient to initiate $CD4^+$ T-cell-mediated GVHD. Interestingly, there was a tissue-specific distribution of GVHD, with recipient DCs being more responsible for skin GVHD and donor DCs potentiating gut GVHD. The pattern of disease in these models was subacute with cutaneous and hepatic features of chronic GVHD.

Persistence of recipient LCs

An important modification of these results was introduced by the demonstration that some populations of APCs, notably LCs of the epidermis, are not necessarily replaced by donor-derived cells following BM transplantation [9]. Under conditions of T-cell depletion, nearly all recipient LCs survive MHC-mismatched transplantation and are able to mediate acute GVHD upon reinfusion of donor T cells and a second inflammatory insult such as irradiation [87,137]. Cutaneous GVHD, in turn, leads to the rapid turnover of recipient LCs and complete donor chimerism [62,87,137]. Persistent recipient APCs may account in part for the breakthrough of T-cell priming and GVHD at high T-cell doses when BM transplantation is used as an experimental means to replace or inactivate APCs [129,130].

The observation that activated T cells are able to clear residual recipient APCs is important since it makes the induction of acute GVHD a self-limiting process. Studies by Sykes and colleagues have explored the conversion of mixed chimeras by donor T cells in detail, demonstrating the essential role of inflammation in controlling access to the tissues [138] and the combined requirement for $CD4^+$ T cells and recipient APCs in mediating a robust graft-versus-leukemia (GVL) effect [139]. Under appropriate conditions, in which priming of alloreactive T cells is confined within the hematopoietic compartment, GVHD pathology can be prevented while allowing full expression of the GVL effect [77]. It remains to be determined whether a similar selective benefit can be obtained by targeted ablation of tissue-resident DCs, particularly those self-renewing populations such as LCs, while sparing visceral DCs in the spleen and liver.

APCs that induce GVHD

A limitation of using HCT to manipulate recipient APCs experimentally is that the identity of the APCs responsible for inducing acute GVHD remains obscure. While it is assumed that DCs play a significant role, PDCs, B cells, or macrophages may also contribute. Recipient "add-back" experiments have demonstrated that DCs are sufficient to induce GVHD in animal models [140,141], although removal of recipient macrophages with clondronate-loaded liposomes has also been shown to attenuate GVHD [142]. In animal models, recipient B cells have negligible or even negative effects on GVHD [140,143]. Alternative APCs are possibly more important in human transplantation, in which polyclonal memory T cells participate in the allogeneic response, than in model systems focusing on naïve T-cell priming to defined antigens. By developing new means to target host macrophages while sparing host DCs, we have recently revisited the role of host macrophages in GVHD [144]. Our data revealed that host DCs and macrophages have opposite contributions to GVHD outcome. In contrast to DCs, host remaining macrophages reduce the expansion of activated donor T cells through their ability to engulf allo-reactive T cells and modulate T-cell proliferation, and consequently limit the severity of GVHD [144]. The immune-modulatory role of macrophages has already been reported in several settings. In tumors, for example, macrophages modulate T-cell function through several mechanisms that include, but are not limited to, the production of inducible NO synthase (iNOS), arginase and indoleamine 2,3-dioxygenase (IDO) [145,146], all of which have all been shown to modulate GVHD after allogeneic HCT [147–151].

GVHD kinetics

From a clinical standpoint, it might be argued that the contribution of recipient APCs to GVHD is entirely predictable based on the simple fact that only recipient APCs are directly activated by conditioning and that classical acute GVHD occurs during or prior to engraftment when the presence of donor APCs is minimal. Although proof is likely to remain elusive in humans, a key role for recipient DCs was argued over 20 years ago in the pioneering studies of Perreault and co-workers [91,123]. Intriguingly, a more recent study showed that the pre-transplant CD14 count is linked to GVHD risk [152] and, as described above, there is clear evidence that recipient tissue DCs survive conditioning therapy [64,88].

Donor T cells and GVHD promote DC engraftment, but the effect of alloreactivity on DC turnover is often ignored in attempts to show that persistent recipient APCs constitute a “risk factor” for developing GVHD. Pre-transplant, every patient has 100% recipient DCs, and after transplant the majority of patients convert to 100% donor-derived DCs. The occurrence of GVHD is linked to a period of rapid conversion from recipient- to donor-derived DCs, which more than likely precedes the onset of clinical symptoms; thus, the faster recipient DCs are lost, the greater is the risk of clinical GVHD. It is therefore very difficult to demonstrate a causal link between persistent recipient DCs and GVHD. For this reason, although it is possible that persistence of recipient APCs correlates with de novo acute GVHD following the withdrawal of immune suppression, it is perhaps just as likely that primed donor T cells, which have already effected complete donor DC engraftment, are the real risk factor. There is currently no evidence for or against either of these mechanisms.

Perhaps a more promising approach to testing the role of persistent recipient DCs in humans is to examine correlations between DC chimerism and GVHD kinetics in cohorts of patients transplanted with regimens of varying intensity. There is no appreciable difference in LC chimerism at 100 days between high-dose and reduced-intensity fludarabine/melphalan transplants, but data are lacking on minimally intensive HCT that show significantly delayed GVHD kinetics [104]. It will be informative to determine whether DC engraftment is similarly retarded. Murine models, which incorporate the added refinement of elective donor T-cell infusion, broadly support this rationale. After a high-dose regimen, the transfer of donor T cells more than 1 month post-transplantation does not generate GVHD [141,153], but after reduced-intensity transplantation in which there is significant myeloid partial chimerism, GVHD can still be induced many months later. Even more directly relevant to these data is the clinical observation of progressive diminution of the toxicity and efficacy of donor lymphocyte infusions with time [121,154]. It has been suggested that the loss of recipient DCs is the cause as described in murine models [77,139], although this is not entirely consistent with human data. DLI is rarely given before 3 months, at which time all patients have at least 90% donor LCs [64] and probably complete engraftment of DCs in other organs. Unless a small percentage of recipient DCs are unusually potent or there is protracted survival of migratory cells in the LNs, other explanations for the reduction of the DLI effect, such as active regulation by donor cells, should be considered [155].

GVHD tropism

One of the major biologic questions concerning GVHD is its tropism for the skin, gut, and liver. It is likely that more than one mechanism explains this predilection. The skin and gut are both important epithelial barriers with commensal flora and dense APC networks. Simply from a numerical standpoint, these organs, together with the BM, spleen, and liver, contain many more F4/80+ resident APCs than the other viscera and skeletal tissues that are generally not affected by GVHD [156]. It is possible that DCs in these sites are also selectively primed by conditioning, either because the epithelia themselves are more readily damaged and release inflammatory mediators (hair loss and mucositis being prominent features of chemoradiotherapy) or because there is greater ingression of microbial products from commensal organisms. In support of the latter argument, there is good evidence for a role of LPS in gut GVHD [96,101,157]. T cells primed in the skin and gut also recirculate to these sites with high efficiency through the induction of specific homing receptors, creating feedback circuits of tissue damage [158]. Studies using bioluminescence dramatically indicate the early involvement of gut and spleen in T-cell priming [159], although in other models the Peyer’s patch itself appears dispensable [160].

It is conceivable that local DC renewal could play some part in the tropism of GVHD for certain organs. Even though splenic and hepatic DCs rapidly prime donor T cells [86], this does not exclude roles for self-renewing DCs in prolonging the initial sensitization phase of GVHD or influencing the spectrum of GVH responses. However, such effects will tend to be subtle and self-limiting since donor T cells, once primed, initiate inflammation, which promotes complete DC donor chimerism. In the skin, persistent recipient LCs are sufficient to generate cutaneous GVHD [87]. The radioresistant LC precursor may indeed be a dermal cell that gives rise to interstitial dermal DCs and LCs, both of which may persist after experimental transplantation [88,122]. Other target organs have not yet been closely scrutinized. The gut and associated Peyer’s patches may harbor radioresistant DC precursors, even though a rapid turnover of mesenteric LN DCs is apparent [62]. In the liver, the bulk of parenchymal DCs rapidly equilibrate with blood DCs [87], but this does not exclude a niche population of cycling DCs in focal GVHD targets such as the portal triad of the liver. The relative importance of persistent recipient DCs may be greater after reduced-intensity transplantation, and it is interesting that atypical patterns of single-organ GVHD are more frequently seen than in myeloablative transplant.

Chronic GVHD

The pathogenesis of chronic GVHD has been difficult to study, for several reasons. Clinical disease is very heterogeneous and animal models are less convincing than for acute GVHD. A number of fundamental features of human chronic GVHD must be explained by any successful model. First, chronic GVHD is delayed, classically to at least 100 days after transplant. Second, prior acute GVHD is a major risk factor, although chronic GVHD is less well controlled by T-cell depletion. Third, the tissue tropism is different from that of acute GVHD, although features of chronic GVHD may rapidly evolve and coexist with severe acute GVHD. Fourth, chronic GVHD has a very different response to therapy, being largely refractory to calcineurin inhibitors but responsive to corticosteroids and also rituximab, thalidomide, extracorporeal phototherapy, and other alternative agents. The features of chronic skin inflammation with sclerosis, mucosal ulceration, salivary and lacrimal gland dysfunction, and chronic hepatitis have parallels with human autoimmune disease. Whether this reflects the same induction process or simply a final common pathway of chronic inflammation is not clear.

From a simple perspective, the delayed onset of chronic GVHD suggests a greater dependence on donor-derived APCs. It has long been held by clinicians and immunologists that engraftment of donor DCs might underlie the progression of acute to chronic GVHD on the grounds that DCs of different origins favor alternative routes of antigen presentation (reviewed in [126]). In mice, acute CD8 T-cell-mediated GVHD dependent on recipient APCs contrasts with subacute forms of $CD4^+$ T-cell-mediated GVHD, which occurs with donor APCs alone [135,136,161]. In the MHC-matched setting, direct MHC class I presentation to CD8 cells is self-limiting and should decline as recipient APCs are removed. In contrast, MHC class II-restricted antigens continue to be presented to donor $CD4^+$ T cells indefinitely by donor APCs. This simple model accounts for the pathologic spectrum of acute and chronic disease by the selection of different minor antigens, potentially with tissue-specific distribution [162], and qualitative differences in $CD8^+$ and $CD4^+$ T-cell-mediated pathology [163,164]. It is easy to add that acute GVHD will accelerate the appearance of chronic GVHD through increased priming of donor $CD4^+$ T cells by activated donor DCs.

More complex models of chronic GVHD invoke thymic dysfunction, principally in terms of defective negative selection [165,166]. Impaired negative selection as a result of acute GVHD has been documented in animals [167]. The merit of this explanation depends on the extent of thymus-dependent immune reconstitution following a transplant. In adult humans, thymic recovery attenuates with age, and mature alloreactive T cells may survive to propagate chronic GVHD completely independently of the thymus [168]. In a number of animal models, mature T cells also mediate chronic GVHD syndromes that are thymus independent [164]. The mechanism of negative selection in the thymus involves BM-derived elements, and the switch from recipient to donor could compromise the availability of recipient mHAs for negative selection, although recipient epithelial elements would still be present. If donor APCs populating the thymus are completely unable to present antigen, as in the case of transplantation with MHC class $II^{-/-}$ BM, a convincing picture of thymic-dependent chronic GVHD is seen [165]. Thymectomy is protective, although this only proves that a dysfunctional thymus can be worse than no thymus at all. This mechanism is perhaps relevant to de novo human chronic GVHD in the younger patient and cautions against attempts to boost thymic function indiscriminately in older patients.

Studies of human DCs in chronic GVHD have revealed a relative depletion of tissue DCs [169] but a higher level of exclusively donor-derived blood DCs, especially PDCs [118]. There are no data on DC chimerism in the tissues, which makes it difficult to exclude a third hypothesis that chronic GVHD is the result of continuous immune activation by rarified long-term surviving recipient DCs. Although in humans all transplants attain at least 90% LC donor chimerism at day 100, just over one-third of patients continue to yield occasional recipient LCs for at least 1 year post-transplant [64]. Chronic allostimulation by these cells might explain the very frequent involvement of the skin and mucosa, often with a focal distribution. The main limitation of this idea is that it cannot account for the increased risk of chronic GVHD in patients with prior acute GVHD, which efficiently ablates recipient LCs. An interesting alternative suggested by results in a murine model is that persistent recipient B cells could contribute to chronic GVHD [170]. This must be tested in humans, and further experiments comparing lesional and non-lesional skin in cases of de novo chronic GVHD are required.

GVL effect

Immunologic protection from relapse, or the GVL response, is likely to be a manifestation of the GVH response in hematopoietic tissue and therefore dependent on the same cellular process of induction [54]. Transient pancytopenia often accompanies DLI responses [171] and is the cardinal feature of transfusion-associated GVHD [172], indicating that BM is indeed a target organ of the engrafting immune system.

Animal models confirm the importance of recipient APCs in the GVL response. Functional recipient, but not donor, APCs are required for a GVL effect mediated by $CD4^+$ and $CD8^+$ cells [131,173]. For a $CD8^+$ T-cell-mediated GVL effect, donor alloantigens must be present on both recipient APCs and tumor; tumor lines expressing costimulatory molecules are also unable to substitute for professional APCs [173]. Of interest, stably engrafted donor APCs, although not required for a GVL effect, are able to mediate some $CD8^+$ T-cell-dependent GVL activity at lower tumor burden while sparing the effect of GVHD [131,139,173].

The GVL effect appears to occur at a lower threshold than GVHD in studies of escalated DLI in mice and humans, suggesting that access to a narrow therapeutic window between GVL effect and GVHD is possible [174,175]. Changing the density or location of host DCs in the recipient may influence the therapeutic advantage in favor of a GVL effect. In murine models, recipient visceral DCs are sufficient to prime robust GVL responses and are readily accessible by donor T cells in the hematopoietic compartment [77,139,173]. In contrast, recipient peripheral tissues are not infiltrated by alloreactive donor T cells in the absence of inflammation [138]. The interaction of donor T cells with visceral, but not peripheral, DC populations may achieve a selective benefit in promoting a GVL effect without GVHD [77,138,139,173]. This argument underpins the logic of delayed T-cell add-back strategies [176] and preemptive DLI [121], which allow the inflammatory insult of conditioning to subside prior to the infusion of donor T cells. It is noteworthy that recent data indicate a more stringent requirement for priming the GVL effect in MHC-matched chimeras than in mismatched transplants. In the matched animals, additional lymphodepletion or Toll-like receptor signaling is required to initiate alloresponses, whereas GVL in mismatched chimeras requires T-cell infusion alone [177]. These results may put new constraints on the efficacy of DLI in humans, although in comparison with mice, humans are significantly lymphopenic post-transplant [169].

Finally, it has been proposed that, in certain malignancies, APCs may arise directly from the malignant clone, serving to prime donor T cells directly to tumor-associated antigens [120]. In chronic myelogenous leukemia, BCR-ABL DCs can be derived in vitro from monocytes [178], but the spontaneous generation of these cells in vivo has never been examined. A similar argument applies to B cells in follicular lymphoma [179]. It is likely that the susceptibility of these diseases to the GVL effect is due not only to efficient priming of donor T cells, but also to the slow kinetics of disease and relatively normal phenotype of the leukemic clone. In other diseases where the GVL response is less effective, relapse can easily occur during GVHD, suggesting that the target cells escape recognition or overwhelm the effectors rather than that there is a fault with T-cell priming.

DCs as potential therapeutic targets in transplant settings

DCs are potential therapeutic targets in the peri- and post-transplant settings. Conventional drugs such as calcineurin inhibitors, mycophenolate mofetil, and glucocorticoids are now known to mediate some of their actions through DC modulation [180–182] and, as described above, conditioning therapy and monoclonal antibodies have profound effects.

A number of novel approaches involving DCs have also attracted interest. The first, suggested 30 years ago, is that ablating recipient APCs might prevent GVHD [123]. The principal objection to this strategy, which parallels the problem of donor T-cell depletion, is that the GVL effect might also be lost. The absence of appropriate APCs indeed diminishes the GVL response in a number of experimental models and provides further evidence that GVHD and the GVL effect are facets of the same process [77,131,141,173]. There is also concern that regulatory T cells might not be formed, diminishing the potential therapeutic advantage [183]. A counter-argument is that different regional populations of DCs may have more or less propensity to induce GVHD, as previously outlined. Prevention of hepatic GVHD by removal of hepatosplenic APCs with liposomal clodronate lends credence to this concept [142]. It is likely that prior cytotoxic therapy of human subjects attenuates GVH reactions, given that a single non-myeloablative dose of cyclophosphamide pretreatment diminishes GVHD in mice [184]. This could explain the relatively high risk of GVHD seen historically in patients with chronic-phase chronic myeloid leukemia compared with patients given induction chemotherapy for acute leukemia, rather than biologic differences in the diseases themselves.

Murine experiments have raised the profile of ultraviolet (UV) irradiation of the skin as a means to accelerate the depletion of recipient LCs [87]. The regional effects of UV radiation may also be complemented by a general immunosuppressive effect [185,186]. However, reservations exist in view of the transient, cytokine-mediated nature of some responses [187] and subsequent recruitment of potent immunostimulatory APCs to the skin [188]. At least one early-phase clinical trial reported increased GVHD, although UV treatment was continued post-transplant, making it difficult to evaluate selective effects of UV radiation in the conditioning phase [189]. An alternative regional therapy is the preemptive use of topical corticosteroids [190]. In contrast, in a more recent study, 17 patients were treated with whole-body UVB irradiation after conditioning with a reduced intensity protocol. Strikingly, all nine patients with complete LC depletion (<1 LC per field) developed only grade I GVHD or no GVHD up to day 100 post-transplant, suggesting that prophylactic UVB irradiation post-transplant is safe and should be further explored as a clinical strategy to prevent acute (skin) GVHD [191].

Modulation of DC activation through the use of C3a receptor (C3aR) and/or C5a receptor (C5aR) blockade may also help reduce alloreactive T-cell immunity and improve GVHD outcome, as recently found in mice [85]. In addition to modulating host DC function, expansion of immunosuppressive macrophages may also provide a useful strategy to improve GVHD outcome. Adoptive transfer of tolerogenic DCs generated in the presence of GM-CSF, IL-10, transforming growth factor beta-1 (TGF-β1), and LPS [192,193], or histone deacetylase inhibitors such as suberoylanilide hydroxamic acid (SAHA) [194] or vasoactive intestinal peptide (VIP) [195], have been shown to reduce GVHD when injected during the peri-transplant setting in mice. We have recently found that pre-transplant administration of CSF-1, a cytokine required for macrophage development, survival and proliferation in vivo, expands the host macrophage pool and dramatically improves GVHD morbidity after allo-HCT [196].

Complementary to the removal of recipient DCs for attenuation of GVH responses is the possibility of stimulating donor immunity by infusing recipient DCs after transplant. This is supported by findings in experimental models [140,141] and could be an important adjunct to DLI, validating the concept of DC-based vaccination for malignancy. One encouraging trial of allogeneic HLA-matched DCs after transplant has already been reported [197]. Such a strategy might be particularly useful in cord blood transplantation, in which there is no access to the donor post-transplant, or when matched unrelated donors prove difficult to trace. Others have shown that regulatory or tolerogenic DCs from the recipient could also be given to treat GVHD in an MHC-mismatched model [193].

In general terms, therapeutic targeting of DC has the potential to control alloresponses beyond means currently available. Antibodies such as CMRF-44 recognize activated DCs in any site and are able to lyse blood DCs and LCs in the presence of complement [82]. Blockade of costimulatory receptors has been advocated for several years as a way of attenuating the initial encounter between DCs and T cells. Newer small molecules such as FTY720, a sphingosine receptor antagonist, have specific actions on DCs, preventing migration to the LNs, and a selective effect on GVHD has been reported with this drug [198]. Inhibitors of Flt3 may also target DCs since the Flt-3 receptor, which is related to c-kit and CSF-1, appears to be required for the differentiation and maintenance of DC populations [199]. Flt-3 inhibitors have shown some activity in ameliorating experimental autoimmune encephalomyelitis [200]. Another novel compound, NK026680, has been reported to interfere with DC activation [201].

Conclusion

The prominent role of recipient APCs in initiating GVH responses and the importance of the GVL effect in eradicating human malignancy have galvanized efforts to understand the homeostasis of peripheral DC populations. Many questions remain, such as the identity and location of the principal APCs in the GVH response, especially in fully complex immune systems. Elegant results have been achieved in animals by isolating different components of the GVH reaction, and new methods to manipulate APCs in vivo are evolving. However, proof that DC-targeted therapy can improve the therapeutic benefit of the GVL response in relation to GVHD has not yet been obtained.

CHAPTER 18

The Experimental Basis for Hematopoietic Cell Transplantation for Autoimmune Diseases

Judith A. Shizuru
Stanford University School of Medicine, Stanford, CA, USA

Introduction

Autoimmune diseases (ADs) are a heterogeneous group of disorders that affect an estimated 5–8% of the US population – 14–22 million persons [1,2]. These diseases occur when antigens within the body of an individual, called self-antigens, become targets of destruction by the immune system. Classically, both T- and B-cell responses are involved. Theoretically, all tissue types can be targets of autoreactivity and more than 80 clinically distinct ADs have identified. However, it is not known why certain organs are involved more commonly than others. Six of the most common ADs are listed in Table 18.1 and include rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), type I diabetes mellitus (T1DM), Graves disease, multiple sclerosis, and pernicious anemia. Collectively, these diseases represent ~50% of the ADs [3]. Autoimmune responses are generally sustained, persistent with manifestations of chronic tissue damage (presumably because self-antigens are continually produced on the targeted tissue), and, in severe cases, diminution of the response does not occur until the cells expressing the autoantigens are destroyed. Around four decades ago it was demonstrated that transfer of hematopoietic cells can alter the course of ADs in rodents. Bone marrow transplantation (BMT) experiments were shown to transfer disease from autoimmune prone rodents to unaffected ones [4–6] and, conversely, to prevent disease if the hematopoietic cells were transplanted from unaffected to susceptible rodents [5,7–9]. The goals of this chapter are to provide a basis for understanding how and why hematopoietic cell transplantation (HCT) may effectively treat severe ADs and to describe the preclinical studies that have contributed to this understanding. Clinical updates are provided in Chapter 67. This chapter begins with an overview of how normal antigen-specific immune responses develop, followed by a discussion of why autoimmunity occurs. Thereafter, studies on preclinical models using HCT for the treatment of autoimmune syndromes are presented.

The immune response

Induction and perpetuation of immune responses

Autoimmunity arises when there is dysregulation of the antigen-specific “adaptive” immune response. Adaptive immunity is induced when innate immune cells fail to eliminate a new infection. T- and B-lymphocytes constitute this adaptive arm, but act in concert with cells of the innate immune system to initiate and carry out their maximal effect. Innate immune cells, which include myeloid, natural killer (NK), and phagocytic cells, rely on a relatively limited number of invariant receptors to recognize microorganisms [10]. These receptors recognize simple molecules and regular patterns of molecular structure known as pathogen-associated molecular patterns (PAMPs) that are present on many microorganisms but not mammalian cells. The invariant receptors of innate immune cells include Toll-like receptors (TLRs) and other pathogen recognition receptors (PRRs). In contrast, adaptive immunity is based on clonal selection of lymphocytes that express a diverse array of highly antigen-specific receptors, and the adaptive arm develops immunological memory after an initial response to a pathogen, leading to an enhanced response to subsequent encounters with that same pathogen.

The adaptive response begins with the interaction between a professional antigen-presenting cell (APC) that presents its antigen to naïve $CD4^+$ T cells. Since activation of $CD4^+$ T cells can induce and perpetuate a cascade of downstream effector mechanisms with potentially disastrous consequences, stringent criteria are required for their activation [11–13]. B cells, macrophages, and dendritic cells (DCs) are the professional APCs that take up foreign protein antigens and process them via an intracellular pathway into peptide fragments. The fragments bind to class II major histocompatibility complex (MHC) molecules that make their way to the APC surface. In the presence of pathogens that signal the APC through their TLRs or PRRs, APC are induced to express costimulatory molecules [10]. APCs migrate to the draining lymphoid tissues where they encounter recirculating $CD4^+$ T cells. In order for a naïve $CD4^+$ T cell to be activated, two criteria must be met: (1) the T-cell clone must express the correct T-cell receptor (TCR) that recognizes the peptide bound to a self-MHC class II molecule; and (2) recognition and binding via the TCR must accompanied by simultaneous delivery of a costimulatory activating signal(s). In the absence of costimulation, TCR engagement can lead to T-cell anergy – a state of unresponsiveness to the antigen [14]. Only professional APCs that both express high levels of class II MHC molecules and express costimulatory molecules effect T-cell activation. Costimulatory molecules expressed by APCs include B7-1 (CD80) and B7-2 (CD86) – the ligands for CD28, CD40, inducible costimulator ligand (ICOS-L) and various adhesion molecules [12,13,15]. APCs, and in particular DCs, demonstrate phenotypic and functional plasticity, and the expression of these functional differences when encountering naïve T cells determines whether or not the encounter will result in the induction of immune reactivity versus tolerance [16]. The environmental milieu in which a T cell encounters

Table 18.1 Associations of HLA type with susceptibility to autoimmune disease

Disease	Affected organ	HLA association	Relative risk[a]
Ankylosing spondylitis	Joints	B27	87.4
Graves' disease	Thyroid	DR3	3.7
Multiple sclerosis	Central nervous system	DR2	4.8
Type I diabetes mellitus	Pancreatic islets	DR3/DR4 heterozygote	~25
Rheumatoid arthritis	Systemic/joints	DR4	4.2
Systemic lupus erythematosus	Systemic	DR3	5.8

[a] The relative risk calculated by comparing observed number of patients with the HLA allele with the number that would be expected, given the prevalence of the HLA allele in the general population.

an APC also influences the outcome. Specifically, the cytokine environment can skew the commitment to certain effector pathways, resulting in polarization of T-cell responses.

Following TCR binding plus costimulatory signaling, naïve CD4$^+$ T cells respond by rapidly proliferating and differentiating. As part of this process, they begin to express new receptor molecules and synthesize and secrete a number of chemokines and cytokines that constitute "signal 3" required for a continued response. Under the influence of signal 3, T-cell clones can expand and develop into distinct effector phenotypes. At least five CD4$^+$ effector phenotypes have been characterized (and the list continues to grow) based on their distinct cytokine-secretion patterns, which activate unique downstream cellular responses [17–19]. These subtypes are designated T-helper type 1 (Th1), T-helper type 2 (Th2), and T-helper type 17 (Th17), T follicular helper cells (Tfhs), and regulatory T cells (Tregs). Th1 development is induced when signal 3 is interferon (IFN)-γ and interleukin (IL)-12, and Th1 cells themselves produce large amounts of IFN-γ. Effector cells of Th1 immunity are macrophages, CD8 T cells, B cells, and IFN-γ-producing CD4 T cells. Th1 responses are particularly effective in protection against intracellular pathogens, including viruses and bacteria, and also tumor cells. Th2 cells are induced by IL-4 and secrete IL-4, IL-5, IL-10, and IL-13. Th2 cells recruit and activate eosinophils, mast cells, and basophils and promote class switching of B cells to produce immunoglobulin E (IgE). Their primary role is in the control of parasites. Th17 are triggered by IL-6 and transforming growth factor beta (TGF-β). They secrete IL-17, IL-17A, IL-17F, IL-21, and IL-22 and play an integral role in both tissue inflammation and activation of neutrophils to combat extracellular bacteria. The fourth subset of CD4 cells is now credited with being the primary population that provides B-cell help for high-affinity antibody production, not Th2 cells as was previously thought [18]. Tfhs mediate antigen-specific naïve or memory B-cell activation, and secrete cytokines characteristic of both Th1 and Th2 cells. They are identified by their location in the B-cell follicles of lymphoid organs and their constitutive expression of CXCR5.

Unlike the other four subtypes that respond to help clear pathogens, the fifth subtype, regulatory T cells (Tregs), suppress T-cell function, and have a primary role in limiting immunity and preventing autoimmune responses [20]. Tregs are a heterogeneous group of cells with different developmental origins [21]. Natural Tregs develop in the thymus and seem to be selected by high-affinity binding to MHC molecules containing self-peptides, whereas peripherally derived Tregs are found in both systemic and mucosal immune systems. Both CD4$^+$ Treg subsets express CD25 and the forked/winged helix transcription factor (FoxP3) [22], which interacts with other transcription factors that would otherwise facilitate activation of non-Treg cells [20]. Both types of Tregs can secrete IL-10 and TGF-β. IL-10 inhibits DCs from secreting IL-12, thus impairing their ability to promote T-cell activation and Th1 differentiation. Natural Tregs may also function by direct cell contact inhibition.

Following the activation of naïve CD4$^+$ T cells and their differentiation and proliferation, the downstream effector elements of the immune system are turned on. Regardless of whether or not the effector mechanisms involve predominantly a cellular or antibody-mediated response, during a normal immune response once the pathogen is destroyed the immune response ceases, leaving only an expanded cohort of memory lymphocytes. However, in autoimmunity, the self-antigen cannot be easily eliminated. Hence the mechanisms that normally function to limit the extent of an immune response do not apply to ADs. Instead, ADs tend to evolve into a chronic state.

Control of immune reactivity

To guard against the development of autoreactivity during the course of defending host tissues, several check points exist to prevent unwanted lymphocyte activation. These mechanisms are generally categorized as central versus peripheral tolerance

Central tolerance

During development, T and B lymphocytes undergo a rigorous selection process to delete potentially self-reactive cells [23,24]. Hematopoietic stem cells (HSCs) give rise to all lymphoid progenitor cells. For T cells, the progenitors migrate to the thymus and traverse this specialized microenvironment which permits T-cell maturation, clonal expansion, and clonal selection. In the thymic cortex, developing T cells (thymocytes) are positively selected in such a way that only those thymocytes whose TCRs can engage peptide–self-MHC complexes on cortical epithelial cells survive and mature, giving rise to thymocytes that are restricted to self-MHC. Negative selection primarily occurs in the thymic medulla. This process removes thymocytes whose TCR binds too strongly to self-peptides plus self-MHC, thereby eliminating potentially autoreactive cells. The thymic medullary cells are involved in negative selection of self-reactive thymocytes [25] and are known to express ectopically peripheral-tissue antigens (PTAs) [26]. It has become clear that many (but not all) tissue-specific antigens, such as insulin, are expressed in a subset of dendritic-like cells, and therefore self-tolerance against these antigens can be generated by central deletion. How these "peripheral" genes are turned on ectopically in the thymus is incompletely understood. However, it has been shown that a single transcription factor, AIRE (autoimmune regulator), is responsible for turning on many peripheral genes in the thymus [27]. Studies in mice revealed that defects in the AIRE gene could explain a rare inherited form of autoimmunity – APECED (autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy) which is manifested by destruction of multiple endocrine tissues including insulin-producing pancreatic islets. Highly relevant to the utilization of HCT for the treatment of autoimmunity is the long-standing observation that bone marrow (BM)-derived APCs present in the thymus are at the top of hierarchy of cells that mediate negative selection of developing thymocytes.

Similarly to T cells, immature B cells that express immunoglobulin receptors that bind too strongly to components of self either die within the BM or become impaired in their ability to respond to antigen (anergic) [24,28]. Deletion occurs at the immature B-cell stage, following expression of IgM on the cell surface (sIgM). sIgM has a pentameric structure and deletion of immature B cells of a particular antigen specificity seems to predominate when the interacting self-antigen is multivalent, indicating that strong cross-linking of an autoreactive receptor causes developmental arrest. Immediate elimination of the B clone is not the only outcome of such strong binding. Autoreactive B cells can be rescued by further gene rearrangements that replace the autoreceptor with one that is not self-reactive. This mechanism is termed receptor editing [28].

Peripheral tolerance

Central deletion is imperfect and self-reactive clones can escape elimination and enter the circulating pool. Moreover, by virtue of the T-cell selection process itself, only strongly autoreactive clones are eliminated and those that recognize self-MHC molecules plus foreign peptides are positively selected. Thus, many lymphocytes have some degree of low affinity for self-antigens. Outside the thymus in the "periphery" several mechanisms to avoid lymphocyte autoreactivity are utilized.

Immunologic ignorance and anergy

Most self-proteins are expressed at levels that are too low to serve as targets for lymphocyte recognition and thus cannot serve as autoantigens. It is likely that only very few self-proteins contain peptides that are presented by a given MHC molecule at a level that is sufficient for effector T-cell recognition but too low to induce tolerance. Lymphocytes able to recognize these rare antigens will be present in the individual but will not normally be activated; they are said to be in a state of immunological ignorance [29,30]. Most autoimmunity likely reflects the activation of such immunologically ignorant cells that occurs when the threshold of reactivity is altered by antigen presentation and milieu in which the events take place.

Stimulation of an antigen specific receptor which in the case of T-cells occurs in the absence of costimulation and for immature B-cells when their sIgM encounters a weakly cross linking antigen of low valence such as a small soluble protein, enter a state of long-lived functional unresponsiveness known as anergy [13–15,31]. Anergy in T-cells involves an acquired blockage of the TCR signaling pathways and anergized T-cell clones produce negligible amounts of IL-2, which is crucial for clonal expansion following T-cell activation. Anergy can be overcome by elevated levels of exogenous IL-2 during re-stimulation [14]. Anergic B cells cannot be activated again by their specific antigen, even with help from antigen-specific T-cells.

Regulation or suppression

Unwanted immune responses can also be controlled by populations that suppress lymphocyte activity. $CD4^+CD25^+FoxP3^+$ Tregs [20,22,32,33] have been shown to inhibit a variety of immune responses both in vitro and in vivo. Treg suppression differs from other forms of self-tolerance because Tregs can suppress lymphocytes that recognize antigens different from those recognized by the Tregs themselves, provided that the antigens are from the same tissue or are presented by the same APC. Two types of Tregs have been experimentally defined. "Natural" Tregs are moderately autoreactive $CD4^+CD25^+FoxP3^+$ that escape thymic deletion and respond to self-antigen by inhibiting other cells. "Peripherally derived" Tregs develop in tissues when antigens are recognized on "immature" DCs that produced TGF-β in the absence of pro-inflammatory cytokines. The importance of Tregs in the maintenance of immune tolerance is evident from the fact that humans and mice that carry the mutation for the master regulator transcription-factor in Treg development, FoxP3, develop severe systemic autoimmunity known as the IPEX syndrome (immunodysregulation polyendocrinopathy enteropathy X-linked syndrome).

A regulatory role for B cells in autoimmune diseases was first reported by Janeway and colleagues in a murine model of multiple sclerosis [34]. Like Tregs, Bregs are a source of inhibitory cytokines such as IL-10 and TGF-β [35]. The issue of how to identify these cells by surface markers or transcription factors, and whether or not Bregs exist naturally in humans, is yet to be resolved [35].

Natural killer T cells (NK-T cells) that express both NK receptors and TCRs qualify as belonging to a heterogeneous population termed NK-T cells with regulatory functions [36]. The most prominently studied subclass are termed invariant natural killer T cells (iNK-T cells) since their TCR diversity is very limited owing to their expression of a single α-chain (Vα 14–Jα 18 in mice, Vα 24–Jα 18 in humans) coupled with a β-chain rearranged with limited Vβ gene segments. NK-T cells recognize glycolipid antigens presented by a monomorphic glycoprotein CD1d. Upon activation, iNKT cells produce large amounts of IL-4 and IFN-γ, and may be an initial source of cytokines that polarize T-cell responses, particularly in the direction of Th2 cells. iNK-T cells have been shown to suppress autoimmunity in animal models, and also graft-versus-host disease (GVHD) responses [37–39].

Autoimmune pathology

ADs arise when immune effector cells cause damage to tissues. The response may be organ specific or systemic, and more than one autoimmune syndrome can exist in an individual Classically, loss of tolerance to self-antigen(s), such as insulin in the case of T1DM or DNA in the case of SLE, are invoked as the triggering events. However, for the inflammatory bowel diseases (Crohn disease, ulcerative colitis), the dysregulated immune response is against commensal microbiota resident in the intestines, not against intestinal tissue itself [40]. Histologic studies have shown variability in the apparent causes of tissue destruction since predominance of antibodies, activated by T or B lymphocytes, or non-specific inflammatory cells, can be found in the tissue lesions. On the basis of such studies, it was concluded that different diseases are predominantly mediated by either humoral (antibody) versus cellular driven immune responses. A traditional categorization of immunologic diseases divides this syndrome into four types, designated type I–IV hypersensitivity responses. Type I responses are caused by antibodies of the immunoglobulin E (IgE) isotype and are considered to be allergic responses, not classical autoimmune responses. Types II–IV involve tissue damage. Type II responses are mediated by antibodies directed against the targeted tissue, type III responses by antibody–antigen complex deposition, and type IV by cellular processes. It should be emphasized, however, that these classifications do not illuminate the more fundamental and important issue of what triggers autoimmune responses since, by the time an autoimmune process becomes clinically evident and classifiable by this scheme, the initiating events are obscured by the downstream effector mechanism causing the actual tissue damage. It is therefore more accurate to consider that autoimmunity involves the integrated activity of T cells, B cells, and innate immune cells. For example, $CD4^+$ T cells are almost always required for the production of pathogenic autoantibodies. Conversely, B cells often have a central role in maximal activation of T cells that effect tissue damage.

Genes and environment

Both genetic and environmental factors appear to be required in the development of ADs. Family studies, animal models, and human epidemiologic studies all support the role of these factors in AD susceptibility. The importance of genetic predisposition was first identified by analyses of disease incidence in monozygotic twins. The concordance rates in twins ranges from ~15% for RA [3,41] to a robust ~57% for SLE [3,42]. Comparisons of these rates with disease incidence in the general population predict that genetic predisposition is a dominant factor. For example, the lifetime risk of developing T1DM in the general population in the United States is 0.4%, whereas for monozygotic twins the concordance rate is in the range 30–50% [43,44]. For siblings, the rate is still significantly increased above the general population at ~6% but is lower than for twins. This decrease in sibling concordance rates compared with monozygotic twins suggests that multiple genes contribute to genetic predisposition. Thus, while genetic susceptibility is a dominant factor, the pattern of inheritance of most ADs is complex [1,3]. With the exception of a few known monogenic causes of autoimmune syndromes, the overwhelming majority of autoimmune diseases are inherited as polygenic traits, meaning that they arise from several independently segregating genes that interact in a cumulative way. The oldest and most consistent genetic marker for susceptibility to specific ADs are certain alleles of the genes located within the MHC (Table 18.1). In recent years, genome-wide association studies (GWAS) have provided a long list of other candidate susceptibility genes, albeit the effect of these alleles confers far less risk [45].

Inbred rodent strains exist that reliably develop spontaneous ADs (Table 18.2) with features similar to those of human disease. These animals are highly inbred, and therefore genetically identical. Like human twins, many, but not all, animals in these inbred colonies develop disease. This lack of 100% concordance in genetically identical humans and rodents provides evidence for the essential role of environmental interactions in AD development. Observations made in rodents where environmental elements can be controlled revealed that some of the factors affecting disease incidence include exposure to infectious pathogens and diet [46–50]. For example, a germ-free environment has been shown to suppress or enhance autoreactivity in mice with spontaneously arising forms of multiple sclerosis [51] and diabetes [46], respectively. Furthermore, it is well known amongst investigators who raise non-obese diabetic (NOD) mice, a model for T1DM, that certain common mouse pathogens, such as pinworms, lead to a dramatically reduced incidence of diabetes. Oral ingestion of protein antigens has been shown to lead to marked suppression of systemic humoral and cell-mediated immune responses when animals are later immunized with the same antigen. This phenomenon is called oral tolerance [52]. A high-fat, high-protein diet has been shown to increase the rate and severity of diabetes in NOD mice [53].

Another factor contributing to autoreactivity is sexual dimorphism. Sexual dimorphism refers to a pattern of skewing of disease incidence and/or severity towards one's sex. It has been observed in many human ADs, such as SLE and autoimmune thyroid disease, that human females demonstrate a disproportionately higher incidence than males [54]. Rodents with ADs, such as NOD mice, show a similar pattern of sexual dimorphism. In NOD mice, castration studies [55] and administration of exogenous male hormones [56,57] have shown that sex-related hormones contribute significantly to the dimorphism. Data from human epidemiologic studies confirm the contributions of genetic and environmental factors in AD incidence. Such studies show clear associations with race, geography, and susceptibility to disease. Again using T1DM as an example, the incidence of disease is ~40 times higher in Finland than in Japan [44].

Table 18.2 Animal models of autoimmune disease

Strain or designation	Disease model	Induction/manipulation
NOD mice	Type I diabetes mellitus	Spontaneous
BB rats	Type I diabetes mellitus	Spontaneous
(NZB/NZW)F1 mice	Systemic lupus erythematosus	Spontaneous
MRL-lpr/lpr mice	Systemic lupus erythematosus	Spontaneous
BXSB mice	Systemic lupus erythematosus	Spontaneous
NZB/KN mice	Polyarthritis	Spontaneous
C57BL mice	Multiple sclerosis [Experimental autoimmune Encephalomyelitis (EAE) in rodents]	Induced – Immunize with peptide of myelin oligodendrocyte glycoprotein (MOG)
SJL mice	Multiple sclerosis (EAE)	Induced – immunize with mouse spinal cord homogenate (MSCH)
Buffalo rats	Multiple sclerosis (EAE)	Induced – immunize with rat spinal cord homogenate (RSCH)
Mice – strains variable	Multiple sclerosis (EAE)	Induced – transfer of lymphocytes from myelin antigen- immunized syngeneic donors
DBA1 mice	Rheumatoid arthritis	Induced – immunize with type II collagen
Buffalo rats	Rheumatoid arthritis	Induced – administer Freund's adjuvant

MHC genes and susceptibility to ADs

The most established genetic association for predisposition to ADs is the genotype of the MHC [58]. This association was noted in the mid-1970s. Initially, correlations were made with the class I MHC type and the spondyloarthropathies. Ankylosing spondylitis, an inflammatory and presumably AD of vertebral joints, was found to be strongly associated with the class I human leukocyte antigen (HLA)-B27 allele, conferring a ~90–100 times greater chance of developing this disease. Later, the emphasis shifted to associations with class II rather than class I MHC molecules, since frequent associations were found in subsequent studies with class II gene products and other ADs, such as Graves disease and T1DM (Table 18.1]. In the last 30 years, the technology of HLA typing has advanced from serologic assays to the more sensitive molecular-based assays that detect variations of the nucleotide level (see Chapter 10). As this technology for HLA genotyping has become more precise, allowing examination of specific regions of the MHC, the associations have become stronger. For example, it has been observed that up to 95% of white subjects developing T1DM express the HLA alleles DR3 or DR4 compared with about 40% of normal individuals, and that individuals heterozygous for both DR3 and DR4 have the highest risk of T1DM development [59]. Subsequent to these observations, it was learned that the association between T1DM and the DR3 and DR4 alleles is due to the tight linkage between DR with DQ alleles, and that the DQβ alleles actually confer susceptibility to the disease [60]. A similar evolution in the association of HLA-type and disease susceptibility has occurred for Graves disease. Graves disease was amongst the first autoimmune disorders noted to have an association with HLA haplotype and the initial association with the MHC class I genotype HLA-B8. Later, however, it became evident that stronger association was with HLA-DR3, which is tightly linked to HLA-B8 [61].

Function of MHC in AD pathogenesis

Although genetic associations are firmly established between ADs and defined MHC haplotypes, the way in which these molecules contribute to autoimmune pathogenesis remains hypothetical. MHC molecules play central roles in both T-cell selection and during T-cell ontogeny and in the presentation of antigen to T cells. It has been hypothesized that certain AD-associated MHC haplotypes permit faulty selection of T cells during development and/or allow aberrant presentation of self-peptides to T cells that results in inappropriate T-cell activation [62–64]. The hypothesis that faulty T-cell selection permits autoreactive T cells to escape central tolerance is supported by the observation that the I-A^{g7}, the disease-associated MHC class II allele in NOD mice, binds peptides poorly and may therefore be less effective at driving intra-thymic negative selection. Alternatively, given that binding affinities differ between MHC alleles and peptides, which can affect the conformation of the MHC–peptide complexes seen by T cells, and that polymorphic residues of the MHC molecules can make direct contact with TCRs and thus affect antigen recognition, it is possible that the disease-associated MHC haplotypes make certain self-antigens appear foreign and/or the haplotypes generate a strong enough immune response to self-antigen to induce T-cell activation. The above hypothesis presumes that the association of ADs with MHC haplotype derives directly from the function of the MHC gene products. Although this hypothesis has been amply supported by data from both humans and rodents, it is not conclusively proven. Disease association clearly maps to the MHC region; however, contained within this region are a number of other genes. Alternative hypotheses include that the MHC haplotype serves only as a marker and that the true (and as yet undetermined) disease-associated genes are closely linked to the MHC alleles.

Non-MHC genes and susceptibility to ADs

The importance of genetic predisposition in AD susceptibility and the conclusion that several genes contribute to an AD phenotype have motivated the search for predominant non-MHC susceptibility genes. To achieve this goal, international coalitions have been formed aimed at collecting large cohorts of families afflicted with specific ADs and employing state-of-the-art technologies to perform genome-wide analyses to locate and identify susceptibility genes. Analyses of such GWAS data have confirmed the complex nature of genetic associations with autoimmunity and the importance of MHC-linkage. In addition, hundreds of non-MHC loci have been identified but have only modest or fairly weak effects [65]. Nevertheless, some loci that show associations with multiple diseases reveal categories of associated genes that, in turn, implicate involvement of particular functional pathways (Table 18.3). These pathways include the intracellular signaling that drives the activation of T and B cells, signaling by cytokines and cytokine receptors, and pathways that mediate immunity and microbial responses [45,65].

Two widely cited examples from GWAS of non-MHC genes with polymorphisms associated with risk of developing multiple autoimmune diseases are protein phosphatase non-receptor type 22 (*PTPN22*) and cytotoxic lymphocyte-associated protein (*CTLA-4*) [45,65]. *PTPN22* encodes an intracellular tyrosine phosphatase that modulates T-cell receptor signaling and is crucial in setting the threshold for thymic negative selection. Knockout of the murine homolog of *PTPN22* results in hyperactive T cells. Single nucleotide polymorphisms (SNPs) of *PTPN22* are associated with human T1DM, SLE, RA, and Graves disease. This clustering of genetic risk factors for many autoimmune diseases suggests that these diseases might share, at least partly, similar underlying causal mechanisms. CTLA-4 is a surface molecule produced by activated T cells that acts as a negative regulator through its binding to the inhibitory costimulation molecules, and has a central role in the maintenance of peripheral tolerance [66]. *CTLA4* polymorphisms have been associated with T1DM, RA, celiac disease, and alopecia areata, again supporting the idea that dysregulation of a central gene pathway involved in lymphocyte signaling thresholds can be a common link to autoimmune pathogenesis (Table 18.3) [45].

Leveraging the information obtained via GWAS is in its early phase, and many concerns have been voiced regarding the utility of such studies. One focus of concern is that most of the loci identified

Table 18.3 Selected non-MHC major associations with autoimmune diseases

Candidate gene	Possible function and mechanism of action	Chromosome location	Autoimmune diseases
Lymphocyte activation and intracellular signaling			
Protein tyrosine phosphatase non-receptor type 22(PTPN22)	Modulation of lymphocyte receptor activation	1p13	T1DM, RA, SLE, Graves disease, Crohn disease[a]
Cytotoxic lymphocyte-associated protein (CTLA4)	Transmission of inhibitory signals in T cells	2q33	T1DM, RA, celiac disease, alopecia areata
Cytokines and cytokine receptors			
Interleukin 2/21 gene region	T-cell trophic growth factors; multiple associations flanking both cytokines	4q26	T1DM, RA, celiac disease, Crohn disease, ulcerative colitis
Interleukin-7 receptor (IL7R)	Differentiation/activation of T cells affected by IL-7 signaling	5p13	MS, primary biliary cirrhosis, alopecia areata
Innate immunity and microbial recognition			
Nucleotide oligomerization domain 2 (NOD2)	Sensing of bacterial peptidoglycan in nuclear factor κB activation	16q12	Crohn disease
Interferon regulatory factor 5	Inducement of interferons, regulation of activation of pattern recognition receptor	7q32	SLE, RA, systemic sclerosis, primary biliary cirrhosis
Transcription factors			
Signal transducer and activator of transcription4 (STAT4)	Mediation of multiple cytokine signals, including interleukin-12	2q32	SLE, RA[b], primary biliary cirrhosis[b], systemic sclerosis

[a] A potentially distinct association within this implicated genetic region has been shown for this disease.

[b] Genetic associations with this disease have been observed in patients of Asian or European ancestry.

are non-coding, and many are far from discovered genes; therefore, they are not immediately informative for experimental work. However, a recent report by Lee et al. [67] provides an example of the integration of genetic, clinical, and functional data in mice and humans to shed light on the pathway influenced by a non-coding SNP. By using a resource of local genotyped controls, they showed that one specific allele of a non-coding SNP correlated with the activity of FOXO3, a transcription factor found in APCs and T cells. FOXO3 downregulates TNF and other pro-inflammatory cytokines in response to lipopolysaccharide (LPS) and other TLR-4 ligands, and conversely, upregulates IL-10, an anti-inflammatory cytokine in response to TLR stimulation. These results were consistent with the more indolent clinical course observed in patients with Crohn disease who carry this SNP haplotype. Hence in the future we can look forward to extending the application of GWAS to encompass genetic influences on disease outcome, independent of the usual focus on disease susceptibility.

Monogenic ADs

Most ADs occur due to the combined effect of multiple genes. However, there are a few known monogenic ADs. These diseases are usually recessive or X-linked. Although the human syndromes have been recognized for decades, discovery of the controlling genes has occurred within the last 15 years and was made possible by studies in mice wherein gene manipulation was used interrogate the gene effect. These syndromes are described in detail later in the section Genetic engineering of ADs.

What triggers autoreactivity?

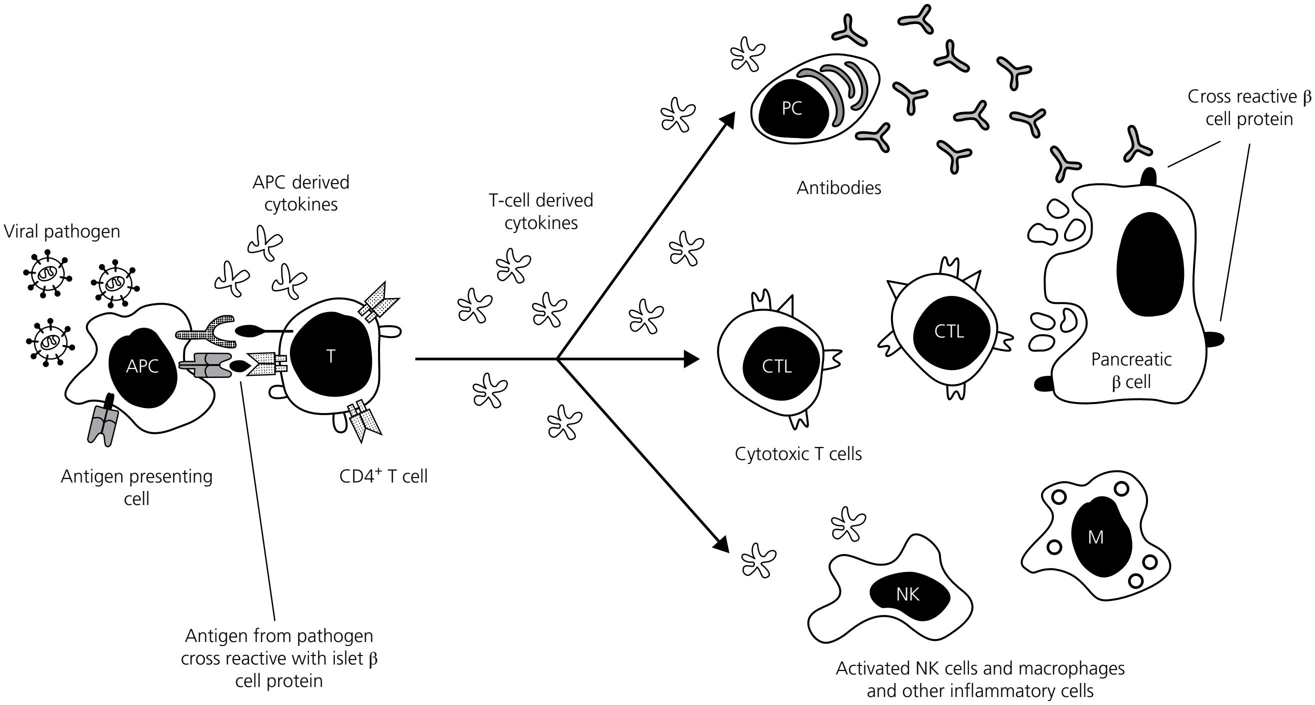
Several hypotheses exist to explain what triggers and perpetuates AD pathology. Although lymphocytes undergo a rigorous selection process during development to eliminate high-affinity self-reactive clones, most circulating lymphocytes have low affinity for self-antigens but make no response to them. These latent, potentially self-reactive, cells can be recruited into autoimmune responses if their threshold for activation is lowered by coactivating factors. Inappropriate presentation of antigens to T cells via activated APCs can occur in many settings, including infection or non-specific tissue trauma. It is generally thought that few self-peptides can trigger a cascade of cellular events that results in targeted tissue damage [63,68,69]. Experimental data show that immune response against a self- or foreign protein is usually focused on one or two peptide sequences (called epitopes) contained within that protein, which are termed *dominant epitopes*. Once a response is triggered against the dominant epitope, other peptide epitopes from the same protein become targets, thus expanding and perpetuating the immune response (Figure 18.1). This hierarchical extension of an immune response from a dominant to a subdominant epitope is termed epitope spreading [69]. Most self-peptides also cannot serve as autoantigens simply because they are present at levels that are too low to be detectable by naïve T cells. However, a few self-peptides that failed to induce tolerance may be present at high enough levels to be recognized by T cells. These peptides are likely the breakdown products of tissue-specific proteins, and it is thought that only certain proteins can act as autoantigens since there are relatively few distinct autoimmune syndromes, and individuals with a particular AD seem to recognize the same antigenic targets. Thus, autoimmunity can occur if an APC presents a dominant epitope of a self-protein on conjunction with activating costimulatory molecules resulting in activation of CD4$^+$ T cells. For example, autoreactive B cells appear to capable of driving this process in SLE by internalizing antigens bound through their antigen receptor and presenting the derived peptides to T cells, elaborate pro-inflammatory cytokines, and organize ectopic lymphoid tissue [70,71]. In a "normal" immune response elicited by exogenous pathogens, elimination of the pathogen would result in cessation of the response. However, in autoimmunity, self-antigens generally cannot easily be eliminated because they exist in vast excess or are ubiquitous, as is the case of the SLE autoantigen chromatin. Hence ADs tend to evolve into a chronic state.

Two predominant hypotheses on how spontaneous autoreactive cells can be induced to respond are by *molecular mimicry* or *tissue injury*. The hypothesis of *molecular mimicry* (shown in Figure 18.1) suggests that immune responses directed against infectious agents can cross-react with self-antigens, causing autoimmune destruction. Thus, the inciting antigen could be a bacterium- or virus-derived protein that shares an amino acid sequence with a prevalent tissue-specific protein. Antibodies or cytotoxic T cells directed against the pathogen will also selectively destroy the normal tissue that expresses the cross-reactive protein. There are clear examples of rodent neurotropic viruses, such as Theiler's murine encephalomyelitis virus (TMEV) and mouse hepatitis virus (MHV), which infect neurons and other cells within the central nervous system (CNS) that result is dysregulation of antiviral immune mechanisms and culminate in the development of autoimmunity [72]. In certain mouse strains, intracranial injection of TMEV results in a self-limited infection, whereas in other strains, TMEV infection results in a chronic demyelinating disease resembling multiple sclerosis. In this TMEV-induced demyelinating disease, autoimmunity can be worsened by engineering the virus to express a known immunodominant peptide of a spinal protein, myelin proteolipid protein. In human multiple sclerosis, Epstein–Barr virus (EBV) and measles virus (MV) have been implicated in the pathophysiology; however, a precise causal relationship between these viruses and multiple sclerosis has yet to be elucidated [72].

The *tissue injury* hypothesis attributes activation of localized inflammatory mechanisms in response to organ injury as the inciting event. During inflammation, the release of chemoattractants and cytokines recruits APCs, lymphocytes, and other effector cells. The result may be release of tissue-specific antigens and uptake by APCs that can result in presentation of self-antigen at high enough levels to act as an immunogen. The two hypotheses are not mutually exclusive as virus infection and direct damage to target tissues such as the CNS or pancreatic β cells could lead to localized inflammation and death of normal parenchymal cells. In this setting, presentation of cellular antigens that are not normally presented in the context of costimulatory signals and cytokines could incite activation of a few bystander autoreactive clones.

Animal models of ADs

Rodent models of ADs have contributed significantly to the understanding of disease pathogenesis. Three major types of animal ADs serve as models for study: (i) ADs that arise spontaneously; (ii) ADs that are induced by antigen immunization or by adoptive transfer of autoreactive mature immune cells; and (iii) ADs that are created by genetic engineering technology. Many of the concepts regarding the causes of autoimmunity have either originated from or been confirmed by observations made in these animal models. Examples of these models and their homologous human diseases are shown in Table 18.2. The models rely on genetic homogeneity so that recipients and donors are from highly inbred strains.



Viral pathogen
APC derived cytokines
T-cell derived cytokines
APC
T
Antigen presenting cell
CD4⁺ T cell
Antigen from pathogen cross reactive with islet β cell protein
PC
Antibodies
Cross reactive β cell protein
CTL
CTL

Pancreatic β cell
NK
M
Activated NK cells and macrophages and other inflammatory cells

Figure 18.1 Induction of autoimmunity. Schematic illustration of events thought to cause an autoimmune response according to the hypothesis of molecular mimicry. An activated antigen-presenting cell (APC) internalizes a pathogen and presents a peptide derived from the pathogen to a naïve CD4$^+$ T cell by a disease-associated class II major histocompatibility molecule (MHC) on its surface. The peptide sequence cross-reacts with a component on pancreatic islet β cells. The CD4$^+$ T cell is activated upon receipt of this first signal by its cognate antigen and costimulatory signals from the APC. Following activation, CD4$^+$ T cells then activate downstream effector mechanisms through direct cell–cell contact and the secretion of cytokines. The pancreatic β cells are destroyed since they express a protein that contains the same peptide sequence as the inciting antigen. CTL, cytotoxic lymphocyte; M, macrophage; NK, natural killer; PC, plasma cell.

Spontaneously arising ADs

Animals that spontaneously develop autoimmune syndromes have been instrumental in revealing the complex nature of genetic susceptibility to ADs and in understanding the cellular events that lead to tissue destruction. The observations that even amongst inbred animals there is reliable but not 100% development of an autoimmune syndrome underscores the importance of the interaction of genetic plus environmental factors in autoimmune pathogenesis [3,73,74]. The essential role of certain MHC alleles as the primary susceptibility genes, the interactions between other minor susceptibility genes, and the role of T-lymphocytes in driving autoimmune pathogenesis have all been confirmed by studies in these animals. The most extensively studied models of spontaneously arising ADs are mice that develop SLE-like syndromes and NOD mice that develop a disease resembling T1DM.

The lupus-prone mice include the F_1 hybrid of New Zealand black (NZB) and New Zealand white (NZW), designated (NZB×NZW)F_1, MRL-*lpr/lpr* mice, and BXSB mice [73,75]. Like human SLE, these animals develop autoantibodies to nuclear antigens and progressive severe glomerulonephritis. Extra-renal disease manifestations occur variably in the individual models and include lymphoproliferation with both splenomegaly and lymphadenopathy, hemolytic anemia, autoimmune thrombocytopenia, vasculitis, thrombosis, and arthritis. All of these lupus-prone strains exhibit premature thymic atrophy, the significance of which is unknown. In the (NZB×NXW)F_1 model, heterozygosity at the MHC (MHC designation H-2$^{d/z}$) has shown to directly impact on disease severity. Data on the non-MHC genes linked with murine lupus come primarily from the New Zealand hybrid model for which genetic crosses have demonstrated confirmed linkage with ~12 loci from the NZB or NZW strain [3,73]. In MRL-strain mice, homozygosity for the *lpr* or *gld* mutations results in acceleration of lupus autoimmunity [76]. *Lpr* is a spontaneous mutation of Fas (CD95) and *gld* is a mutation of Fas ligand. Binding of Fas ligand to Fas signals Fas-bearing cells to undergo apoptosis. MRL-strain mice have a massive accumulation of lymphocytes and autoantibody production. Although typical SLE patients do not have Fas defects, in the mid-1990s it was determined that a rare human syndrome called autoimmune lymphoproliferative syndrome (ALPS), which resembles MRL/*lpr* mice, was in fact due to Fas mutations [77]. BXSB mice defects carry the Yaa (Y chromosome-linked autoimmune acceleration) gene [73,78], which results in more rapid and severe lupus-like disease in male than female BXSB mice. The skewing towards higher disease severity in male contrasts the more common pattern of severity seen in female (NZB×NZW)F_1 mice, NOD mice, and many human ADs where disease severity is often skewed towards females.

NOD mice develop a syndrome resembling human T1DM and are the most exhaustively studied model of an animal AD [74,79]. The disease pathogenesis begins with the infiltration of mononuclear cells into the insulin-producing islets of Langerhans at ~3–4 weeks of age. Infiltration of the islets progresses slowly over the course of several months until the islets are destroyed and the mice manifest symptoms of hyperglycemia at ~6–9 months of age. NOD mice express only one MHC class II gene product. The sequence of this class II molecule, designated I-A^{g7}, is unique to the NOD strain and it binds peptides poorly – a characteristic which has been suggested to explain the association of this genotype with autoreactivity [62,80]. In addition, gene mapping studies have revealed that >20 non-MHC loci contribute to the disease process [81]. NOD mice are reported to have other immune defects [82,83], including differentiation and functional defects of macrophages, and also defects in Tregs or alternatively the ability of effector T cells to be regulated by Tregs [84]. Progression to overt diabetes can be blocked in these mice by prolonged administration of antibodies directed against $CD4^+$ T cells in the prediabetic phase, demonstrating that NOD disease is $CD4^+$ cell mediated [85,86]. Pathogenic T cells capable of transferring the disease have been cloned from these mice and TCRs from such clones have been expressed in non-NOD background transgenic mice causing diabetes [87–89]. Once hyperglycemia develops, NOD mice are difficult to cure since, like humans, physiologic normalization of hyperglycemia can only be corrected by islet or pancreas transplantation, and such transplantations are vulnerable to immune destruction by both anti-islet specific immunity, and also rejection on the basis of allogeneic differences.

Immunization and cell transfer models of ADs

Conventional strain rodents can also be induced to develop autoimmune syndromes by immunization with proteins or peptides derived from defined tissues, or by transfer of pathogenic lymphocytes (Table 18.2). Genetic susceptibility appears to play a major role since certain strains are more prone to mount pathogenic responses than others. One of the best studied examples of an antigen-induced AD is the rodent disease experimental autoimmune encephalomyelitis (EAE) [90,91]. EAE-affected mice or rats develop symptoms analogous to the human neurologic disease multiple sclerosis. The animals show symptoms of paralysis that, as in multiple sclerosis, can be either progressive or fluctuating in severity. EAE is induced by immunization with components derived from the spinal cord (Figure 18.2). These components range from the emulsified spinal cord itself, proteins derived from the spinal cord, or defined peptides from spinal cord proteins. The proteins that are known to induce EAE in mice include myelin-basic protein (MBP), proteolipid protein (PLP), and myelin oligodendrocyte glycoprotein (MOG). Defined peptides derived from these proteins can also induce EAE, and the exact sequence of such peptides depends upon the MHC haplotype of the mouse strain immunized. For any given mouse strain, only certain peptide sequences are pathogenic and are termed immunodominant. It was the study of the immunodominant peptide in EAE that led to the hypothesis of epitope spreading [68,69] as a mechanism by which immune responses can be perpetuated and expand to other antigenic specificities. In order to induce pathogenic autoimmune responses by immunization with peptides or proteins, it is critical that these antigens be administered as part of a mixture of adjuvants, such as Freund's adjuvant and/or pertussis toxin. Complete Freund's adjuvant is an oil-in-water emulsion containing dead mycobacteria that is thought to enhance immunogenicity in two ways. First, the bacterial products in adjuvant signal the APCs via the Toll pathway resulting in the expression of costimulatory molecules and cytokines, and converting resting APCs to activated and migrating cells [92]; second, emulsification of antigen in adjuvant serves to convert soluble protein antigens into particulate forms, which are more readily ingested by APCs.

Another way to induce ADs reproducibly is by transfer of lymphoid cells from affected to unaffected immunocompetent recipients. Populations capable of transferring disease include cells taken from peripheral lymphoid organs, such as the spleen or lymph nodes [93,94], or cells extracted from autoimmune target tissues, such as infiltrative pancreatic islets in NOD mice. It is also possible to clone pathogenic T cells of a single antigen specificity that can transfer disease [87,95,96]. Cloned T cells are particularly valuable for tracking immune responses in vivo since they express a monotonous TCR that can be identified by labeled monoclonal antibodies (mAbs) that bind the variable region of the TCR β chain (Vβ) or MHC–peptide tetramer complexes that can bind the antigen recognition portion of the TCR. Receptors from such clones can also be used to generate transgenic animals. Interestingly, adult T cells from normal mice that are depleted of $CD4^+CD25^+$ T cells can transfer an autoimmune syndrome with a wide spectrum of organ-specific manifestations including gastritis, oophoritis, orchitis, and thyroiditis [32]. Indeed, these transfer studies were one important means by which the existence of regulatory $CD4^+CD25^+FoxP3^+$ T cells was demonstrated [32,97,98].

Appropriate recipients for adoptive transfer studies are irradiated animals, or genetically immunodeficient strains that cannot produce T- and/or B-lymphocytes [99]. Two prominent examples of naturally occurring mutations that prevent normal lymphocyte development are a defect in DNA repair resulting in mice with severe combined immunodeficiency syndrome (SCID), and a defect in the Wnt signaling pathway, which results in mice that are both hairless and lack a thymus (*nude* mice). Mice with the *nude* defect cannot produce T cells. However, transfer of their hematopoietic progenitor cells to recipients with normal thymuses results in normal T-cell development. Hematopoietic progenitors from SCID mice cannot generate functional T or B cells even in a normal recipient. Genetically engineered knockouts of the recombination activating genes (*RAG-1* or *RAG-2*) required for T- and B-cell receptor rearrangement result in defects phenotypically similar to the SCID mutation in that *RAG-1* or *RAG-2* knockout mice cannot generate functional T or B cells.

Genetic engineering of ADs

Genetically engineered mice that either express molecules at supraphysiologic levels or that have been knocked down for the expression of specific molecules have been generated in order to model and study defined aspects of AD pathogenesis. Numerous varieties of such genetically manipulated mouse strains now exist that have resulted in the generation of animals with altered expression at key regulatory molecules of the immune system [100]. These gene targets include but are not limited to the MHC, lymphocyte receptors, transcription factors, and soluble molecules such as cytokines and chemokines. A category of genetic aberrations that have been particularly informative are those that give rise to autoimmune syndromes as monogenic traits. Included in this category are knockout of the *AIRE* (autoimmune regulator) gene, which results in a decreased expression of self-antigens in the thymus. AIRE knockout mice develop a syndrome of autoimmunity that resembles human APECED [27]. Mutation of the FoxP3 transcription factor, a key differentiation factor for some Tregs, results in the mouse version of the human IPEX syndrome, which is an X-linked trait that presents as immune dysregulation, polyendocrinopathy, and enteropathy [101]. In IPEX, the numbers of $CD4^+CD25^+$ Tregs are comparable to those in healthy individuals. However, the suppressive function of these cells is impaired. Knockout of CTLA-4, the high-affinity inhibitory receptor on T cells for the B7 molecules, results in a fatal syndrome of multi-organ lymphocytic infiltrates and severe enlargement of lymphoid organs consistent with a

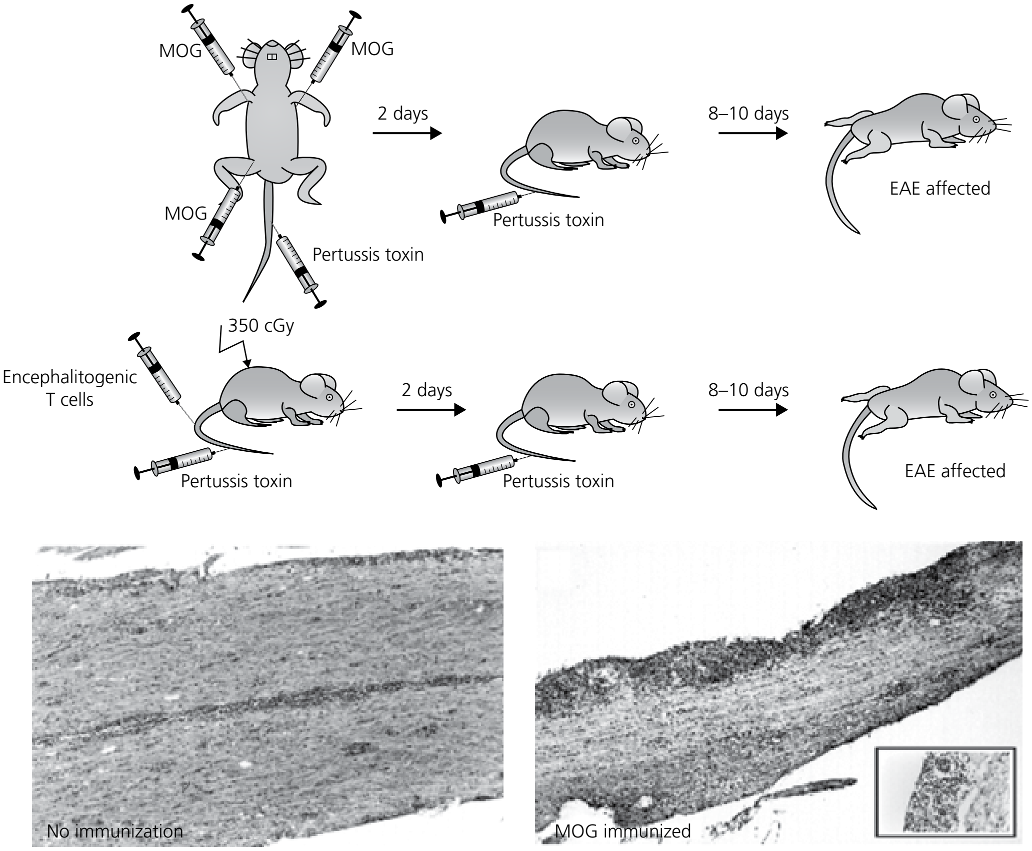

Figure 18.2 Experimental approach to causing an autoimmune disease (AD). Experimental autoimmune encephalomyelitis (EAE), a rodent disease resembling multiple sclerosis, can be induced by immunization of normal mice with components derived from mouse spinal cord. The top panel shows a schematic for EAE induction using a peptide derived from myelin oligodendrocyte glycoprotein (MOG). The peptide is emulsified in Freund's adjuvant. On day 0, the mixture is injected subcutaneously into the inguinal and bilateral axillary regions. Immunized mice receive an additional adjuvant injection (pertussis toxin) by intravenous route on days 0 and +2. Alternatively, encephalitogenic T-cell lines, T-cell clones, or lymphocytes from syngeneic mice immunized with myelin components can be transferred into mice prepared with low-dose radiation plus pertussis toxin on days 0 and +2. EAE is graded on a scale of 0–5 as follows: 0, no clinical signs; 1, loss of tail tonicity; 2, flaccid tail and hind limb weakness; 3, hind limb paralysis; 4, complete hind limb paralysis; 5, moribund or death. The bottom panel shows hematoxylin and eosin-stained spinal cords from (left) a non-immunized mouse as compared with (right) a MOG-immunized mouse. Note that the intense mononuclear cell infiltrate is most prominent in the meningeal areas of the spinal cord of the immunized animal.

systemic autoimmune reaction presumably directed against multiple, as yet unknown, self-antigens. This profound phenotype in mice led to a search for associations of CTLA-4 polymorphisms with human ADs, and the discovery that several such diseases, including Graves disease, T1DM, and other endocrinopathies, show a striking association with a *CTLA4* polymorphism (Table 18.3) [102]. Although animals with these types of monogenic aberrations have been instrumental in revealing the basic biology of autoimmunity, they have not been used for purposes of clinical translation of HCT to the treatment of ADs, hence their use in HCT transplantation will not discussed in this chapter.

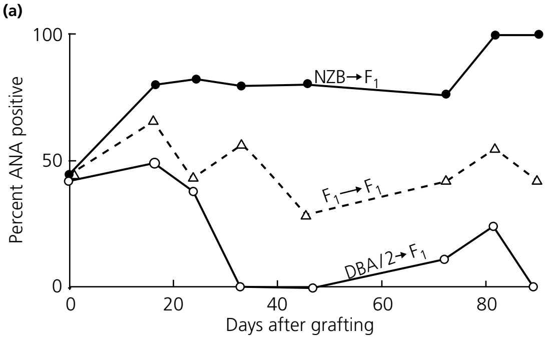
HCT and the treatment of ADs

Historical perspective

Preclinical studies and case reports in the human transplantation literature support the use of HCT for the treatment of severe ADs [103,104]. The clinical literature on this topic (reviewed in Chapter 67) contains several case reports demonstrating that patients undergoing allogeneic HCT for conventional indications (e.g. hematologic malignancy) with a coincidental AD experience long-term improved or even full remission of both disorders. Conversely, there have been case reports of transfer of ADs from AD-affected allogeneic HCT donors into previously unaffected recipients. In evaluating the preclinical literature for its relevance to the treatment of human ADs, it is important to bear in mind that heterogeneity exists among the experimental systems, and that often the studies were designed to answer basic questions about AD pathogenesis rather than to form a basis for direct translation to human therapy. A goal of the early investigators was to establish what cellular elements transfer or prevent disease. Thus, initial studies were directed towards the creation of allogeneic radiation BM chimeras to determine if transplantation of hematolymphoid elements could alter susceptibility to AD in rodents. As early as the 1960s, it was known that certain mouse strains, such as the NZB, develop a syndrome resembling human SLE. In 1969, Denman et al. [6] demonstrated that transfer of BM or spleen cells from NZB mice to MHC-matched non-autoimmune prone BALB/c mice (both H-2^d) resulted in disease in the recipients. Later, in 1974, Morton and Siegel [4] demonstrated that BM transferred into irradiated recipients could, on the one hand, transfer disease from NZB donors into MHC-matched BALB/c or DBA/2 recipients and, on the other, BM from BALB/c or DBA/2 donors could result in transient normalization of antinuclear antibody (ANA) titers in NZB recipients (Figure 18.3) [5]. Donor chimerism was not measured in these studies, and one explanation proposed by the authors for the transient rather than persistent nature of ANA depression was that perhaps only short-term chimerism was achieved in the NZB recipients. Later studies supported this latter idea since permanent allogeneic chimerism appears to be necessary to achieve long-term disease control [105,106]. Following the landmark studies of Morton and Siegel, other investigators confirmed in different SLE models that BM contains the cellular components capable of transferring disease [7,8].

ADs as "stem-cell disorders"

These seminal experiments led to the concept that the etiology of autoimmunity is determined by innate properties of the HSCs and its differentiated lymphocytic progeny, and independent of host environment. Indeed, it was later observed by other groups, and in different animal systems, that the genotypic origins of the BM (i.e. from susceptible or non-susceptible strains) determined whether or not the animal developed or was protected from disease. However, not all studies have been consistent with this concept. For example, NOD disease (diabetes) has been transferred by parental NOD BM into F_1 offspring of NOD mice crossed with different strains [93,107]. However, when NOD BM was transferred into genetically disparate recipients, the radiation chimeras engrafted with NOD BM and developed lymphocytic infiltrates of their islets, but most did not progress to overt diabetes [108]. These data show that while anti-islet reactivity can be transferred by BM, the host environment provides additional elements that permit the perpetuation of an immune response, which ultimately results in tissue destruction. (See also the later section Genotype and susceptibility.)



(b)

Strain or chimera[a]	ANA incidence[b]
Intact DBA/2	0/20 (0%)
DBA/2 ⟶ DBA/2	0/14 (0%)
DBA/2 ⟶ NZB	9/45 (20%)
NZB ⟶ NZB	25/26 (86%)
Intact NZB	59/61 (97%)

[a] Chimeras were established by exposing recipients to 800 to 1000 R when 3 months old, followed by grafting of 3×10^6 bone marrow cells from 3-month-old donors. Mice were assayed 3 months after transplantation or, in the case of intact DBA/2 and NZB animals, when 5 to 6 months old.

[b] Individual plasma samples were diluted 1:20 and assayed for ANA by an indirect immunofluorescence method using chicken erythrocyte nuclei as antigen. Values represent number of mice per total assayed (percent) showing ANA positivity.

Figure 18.3 Seminal study showing that allogeneic bone marrow transplantation reverses autoimmunity in autoimmune prone mice. (a) Breeding of autoimmune prone New Zealand black (NZB) mice with non-autoimmune histocompatible DBA/2 mice yielded (NZB × DBA/2)F_1 progeny with intermediate antinuclear antibody (ANA) production. Lethal radiation of (NZB × DBA/2)F_1 recipients and transplantation with NZB, DBA/2, or syngeneic F_1 bone marrow (BM) showed that mice transplanted with non-autoimmune DBA/2 BM had suppression of ANA reactivity. Neither syngeneic F_1 nor NZB transplants suppressed ANA reactivity. In fact, responses of the different recipient groups displayed remarkable fidelity to donor-type ANA post-transplantation. (b) NZB or DBA/2 mice underwent lethal radiation and transplantation with syngeneic or allogeneic BM. Plasma ANA followed at 3 months post-transplant. Intact control mice were unmanipulated. Only NZB recipients of allogeneic DBA/2 BM showed significant reversal of ANA production. Source: Morton and Siegel 1979 [5]. Reproduced with permission of Lippincott Williams & Wilkins.

The inconsistencies that exist in this literature are not surprising given that autoreactivity arises from a combination of interacting genetic and stochastic factors that affect hematolymphoid cells, and also other tissues. Furthermore, BM grafts are complex mixtures of cells with different functions. Among the populations transferred and generated de novo in a recipient by BM are those that control antigen-specific immune responses – APCs and lymphocytes. APCs express the MHC-restricting elements that are instrumental in shaping the T-lymphocyte repertoire. Hence it is logical that the BM genotype contributes significantly to autoimmune susceptibility. However, the concept that ADs are solely disorders of HSCs is overly simplistic. The other factors that modulate immune reactivity should be considered when interpreting the studies discussed in the following sections.

Rationale for HCT to treat ADs

Both autologous and allogeneic HCT have been studied in preclinical models of ADs. The rationale for efficacy differs between these two procedures. The use of *autologous* HCT is based on the idea that near complete ablation of autoreactive cells, primarily T cells, can be achieved by high-dose therapy followed by rescue with a hematopoietic graft that contains few or no pathogenic cells. Such an approach is analogous to the treatment of cancer wherein the conditioning regimen results in cytoreduction of malignant cells and the patient is "rescued" with a hematopoietic graft that contains none or very few passenger cancer cells. It is thought that the aberrant events that induce autoimmunity (such as infection with virus that cross-reacts with normal tissues) occur only rarely, and the manifestations of disease in AD patients reflect the perpetuation of effector responses which continue even though the inciting event has passed. Therefore, lymphoablation and reconstitution with autologous grafts that lack mature lymphocytes are thought to "reset" the immune system, and the disease will not recur, assuming that the likelihood a second pathogenic event will trigger autoreactivity is extremely low.

The rationale for *allogeneic* HCT is similarly based on the assumption that replacement of a defective immune system with a normal one will eliminate the autoreactive cells. Genetically distinct hematopoietic cells likely express genes that can modify recipient immune responses favoring tolerogenic rather than immunogenetic ones. In addition, mature donor cells (primarily T cells) confer an effect that has been termed "graft-versus-autoimmunity" (GVA), meaning that graft alloreactive cells eliminate host autoreactive cells. There is no expectation that GVA is specific for autoreactive cells, since it is a graft-versus-host effect that can result in broad host T-cell depletion. The majority of preclinical studies favor allogeneic over autologous HCT as the more efficacious approach to blocking autoreactivity. However, the recent multicenter clinical trials of human disease have been exclusively directed to the use of autologous HCT (see Chapter 67) [103,109–111]. The reluctance to perform allogeneic rather than autologous HCT for ADs is based on concerns about unacceptable procedure-related morbidity and mortality in the former as compared with the latter.

Definition of terms and experimental approaches

Autologous, syngeneic, congenic

Genuine autologous HCT has only rarely been performed in rodents because of the pragmatic limitations of harvesting autologous hematopoietic cells from small donors. Instead, syngeneic donors from the same inbred strain as the recipient, or congenic donors that differ from recipients by one or a limited number of non-histocompatibility genes, are used. The advantage of using congenic donors is that the gene difference(s) permits the determination of the origin of hematopoietic cells (residual host as opposed to graft derived) in the transplanted recipient. For example, mice that are identical except for a congenic difference at the CD45 allele are common laboratory tools. CD45 (previously designated Ly5) is expressed on all lineages of hematopoietic cells, and in mice there are two alleles, CD45.1 and CD45.2 [112,113]. mAbs exist that can distinguish between these two alleles. Thus, staining assays employing labeled mAbs, such as fluorescence-activated cell sorter (FACS) analysis or immunohistochemistry, permit the detection of donor-versus-host hematopoietic cells in the transplant recipients. Male into female transplantations or vice versa can also be used, in which case the chimerism analysis involves in situ hybridization looking for the presence or absence of the Y chromosome. Another type of donor has been termed *pseudoautologous*, which means that in models wherein the disease and recipients are induced by antigen immunization [114], the congenic or syngeneic donors undergo similar immunization. Grafts from such donors may contain contaminating mature autoreactive cells with the potential to cause disease, therefore the use of such donors more accurately reproduces clinical autologous HCT. Grafts from congenic or syngeneic donor strains that develop spontaneous disease are not called pseudoautologous, although a similar potential exists to transfer autoreactive cells in unmanipulated hematopoietic grafts. In this chapter, the HCT studies are described as they were originally performed using congenic, syngeneic, or pseudoautologous donors with the understanding that all of these graft types serve as models for autologous HCT.

Genetic differences and measurement of chimerism in allogeneic HCT

By definition, allogeneic HCT uses donors that are genetically disparate from the recipients. Genetic disparity means that the donor and recipients are mismatched at multiple gene regions and are distinct from congenic pairs wherein the genetic differences are limited. Many of the studies were performed between donor and recipient pairs that were derived from distinct ancestral strains, and therefore differed at both MHC and multiple other minor histocompatibility antigen genes. Determination of donor chimerism during the early years was possible using antisera or mAbs in cytotoxicity or staining assays. For transplantations involving MHC differences (MHC-mismatched and haplo-identical), reagents that recognize MHC determinants have been used. Detection of chimerism between MHC-identical strains has been more difficult because the reagents are more limited. In fact, studies that predate the late 1970s when allele-specific mAbs were developed did not evaluate chimerism. The most widely used approach to measure chimerism is antibody-based assays. These assays require that allelic differences exist between strains for gene products expressed on the surface of hematopoietic lineage cells, and that antibody reagents exist that are capable of distinguishing these informative allele markers. Examples of antibody reagents used for this purpose are those that recognize Lgp100 [115], a glycoprotein expressed on lymphocytes of certain strains, or CD45 [112,113], an allelic marker expressed on all hematopoietic cells. An alternative non-surface-staining approach is to utilize polymorphisms identified within the mouse genome [116] and perform polymerase chain reaction (PCR) assays to differentiate hematopoietic cells between MHC-matched strains.

Preparative regimens

In most rodent studies, recipients are prepared for transplantation with lethal radiation. Myeloablative radiation doses are strain specific and require titration studies to determine the dose(s) at which death occurs because of hematopoietic failure, and not other organ toxicities [7,117,118]. Non-uniformity of radiation dose exists in the literature. Because such dose variations affect the level of lymphoablation and the degree of resistance to engraftment of allogeneic hematopoietic cells, radiation dose variability must be taken into consideration when comparing outcomes between different experiments.

The use of non-myeloablative radiation-based approaches in rodent models has lagged behind the studies in humans and large animals. Compared with the explosive development of reduced-intensity and non-myeloablative conditioning protocols in humans, relatively few rodent studies have been performed. However, given the acknowledged concern about the morbidity of conventional allogeneic HCT for the treatment of patients with ADs, the more recent rodent literature tests the idea that with reduced-intensity conditioning the establishment of mixed chimerism may be sufficient to cure ADs.

Chemotherapy that includes reagents used in human patients such as cyclophosphamide (CY) and busulfan (BU) have been employed in studies wherein the goals were to model explicitly clinical transplantation [119,120]. CY is the best studied of the chemotherapeutic drugs in rodents and reports from the early literature show that this agent alone without hematopoietic cell rescue is highly effective at ameliorating manifestations of ADs such as EAE in rats [121] and antibody production and immune abnormalities in SLE-prone mice [122,123]. Dimethyl myleran is an alkylating agent related to BU with profound marrow suppressive activity and little immunosuppression that has been used for rodent HCT preparation [124,125]. Fludarabine, an agent that is widely used in human reduced-intensity regimens, has also been tested in animals. Unfortunately, mice are highly resistant to the lymphoablative effects of fludarabine and its congeners, making it difficult to model homologous reduced-intensity regimens in mice utilizing this drug.

An attractive advantage of working with rodent model systems is the availability of numerous antibody reagents that specifically target immune cell subsets and hematopoietic stem/progenitors. Although there has been no study demonstrating that antibodies alone will effectively allow engraftment of allogeneic HSCs in wild-type animals, there are reports demonstrating that antibody treatment alone can permit engraftment in severely lymphoid-deficient mice [126], and in NOD mice if high doses of $CD8^+$ cells accompanied the BM graft [127]. Cell targeting with mAbs has proven ability to augment engraftment when used in combination with non-myeloablative radiation in NOD mice [128–130] and non-autoimmune strains.

Hematopoietic graft types

Unfractionated or T-cell-depleted (TCD) BM from wild-type donors or BM from mice with the *nude* (*nu/nu*) gene defect have been the graft source in most studies. *Nude* mice are useful as donor animals because they lack *a* thymus [99]. Hence, BM grafts from *nude* mice are not contaminated with T cells, but when engrafted into recipients with functional thymuses, their hematopoietic cells give rise to mature T-lymphocytes. One group of investigators used positive selection by binding BM cells to the plant lectin wheat germ agglutinin (WGA) [131]. The rationale for this approach was that WGA-positive BM cells were enriched for stem and progenitor cells, as well as an immunoregulatory "natural suppressor" population [132]. Highly purified HSCs isolated using a combination of magnetic bead and fluorescence-activated cell sorting for the composite phenotype of $cKit^{+}Thy\text{-}1.1^{lo}Lin^{-/lo}Sca\text{-}1^{+}$ (KTLS) [133,134] (see also Chapter 4) have been transplanted into autoimmune-prone mice [129,135,136]. The T-cell content of KTLS HSC grafts is reduced by >5 logs compared with BM. Of note, the use of KTLS HSCs or other manipulated BM populations in allogeneic transplantations results in marked differences in the level of resistance to engraftment by the host compared with unmanipulated BM. Furthermore, KTLS HSCs lack mature immune cells and therefore do not confer GVA activity. Consistent with this lack of GVA activity, significant amounts of host T cells remain following KTLS HSC transplantations [129,135–138]. Hence graft content has the potential to affect directly the outcome of autologous and allogeneic HCT in the treatment of ADs.

Timing of the HCT procedure

Since the progression of ADs in most rodent models is well characterized, it is possible to choose the time of HCT relative to the expected disease course. For example, in antigen-induced models, immunized animals have been transplanted either before or following the onset of overt manifestations. In spontaneously arising ADs, the transplantations can be performed during the phase when mice have documented abnormalities in immune function but few clinical signs of impairment, or at later disease stages. The studies show that animals are more consistently cured of the ADs if they undergo the HCT procedure at a very early stage of disease, even when there is measurable pathology such as lymphocytic infiltration of islets in NOD mice or evidence of glomerulonephritis in SLE-prone animals, but not at the point when they have suffered end-stage organ damage. If a single organ has been destroyed which is itself replaceable by transplantation, then it is possible to perform simultaneous organ plus HCT transplantation (see Chapter 12). The best example of this approach in AD-affected animals has been in older NOD mice that have undergone simultaneous allogeneic HCT plus donor-matched pancreatic islets in order to cure them of overt diabetes [128,129,139].

Autologous HCT

Proof of concept

The preclinical literature contains conflicting reports regarding the efficacy of syngeneic HCT in curing autoimmune syndromes [7]. Until the late 1980s, it was generally believed that syngeneic HCT would have no effect on AD pathogenesis. In fact, mice transplanted from syngeneic donors served as negative controls in allogeneic HCT studies to differentiate the effects of the preparative regimen alone from the effects of the allograft – a logical conclusion since syngeneic grafts were thought merely to perpetuate ongoing tissue destruction unless complete elimination of pathogenic cells was achieved. Indeed, in many studies [4,129,135,140–142], the animals in the syngeneic control group showed no amelioration of disease whereas allogeneic HCTs were curative. However, a series of reports emerged beginning in 1989 from van Bekkum and colleagues demonstrating that significant remissions could be achieved with syngeneic transplantation in rats affected with antigen-induced ADs [7,143]. In the original studies of arthritis caused by Freund's adjuvant, the syngeneic BMT "control" group was unexpectedly noted to show equal resolution of disease as the allograft recipients (Figure 18.4) [143]. Interestingly, rats that had undergone syngeneic

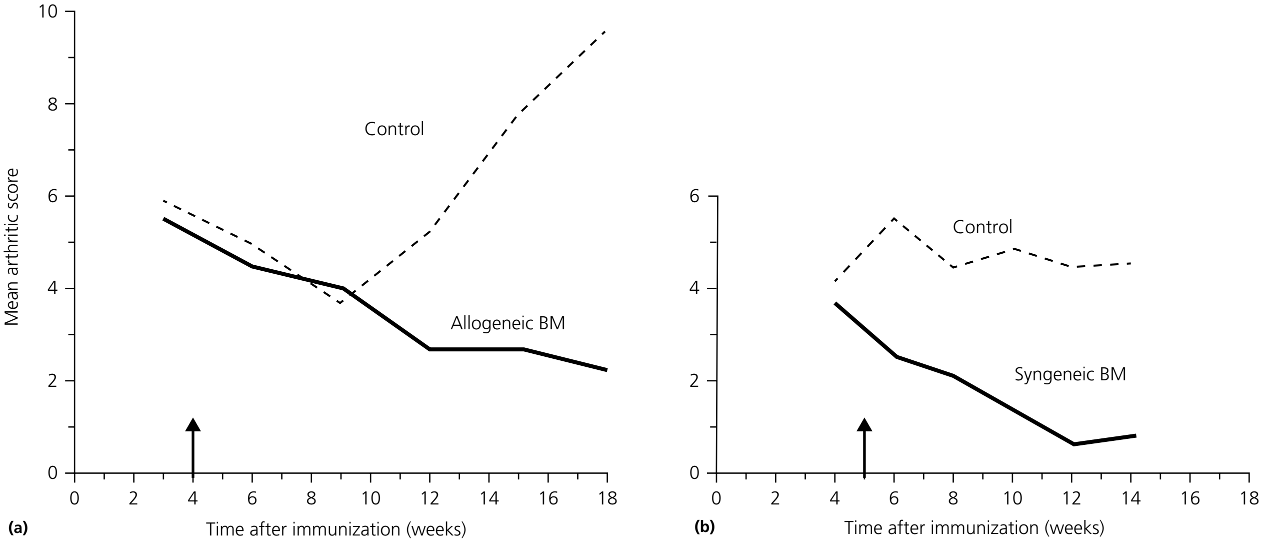


Figure 18.4 Seminal study showing that syngeneic and allogeneic bone marrow transplantation reverses autoimmunity in rats with adjuvant-induced rats arthritis. (a and b) Chronic adjuvant arthritis was induced in male Buffalo rats by inoculation with *M. tuberculosis*. Rats were divided into two equal groups: (i) animals with no further treatment, controls; (ii) animals irradiated (8.5 Gy TBI) and transplanted with bone marrow (BM) cells [(a) syngeneic; (b) allogeneic (MHC-mismatched). Arrows indicate the time of transplantation. Results are expressed as the arithmetic mean of the arthritic score. Source: van Bekkum et al. 1989 [143]. Reproduced with permission of the National Academy of Sciences of the United States of America.

BMT prior to arthritis induction with adjuvant developed disease that was equivalent in frequency and severity as in naïve rats, whereas reimmunization of rats that were disease affected at the time of syngeneic BMT did not reinduce disease. Later studies reproduced this observation that syngeneic BMT is effective only after antigenic challenge and immunity has occurred and not before immunization [144]. These data suggest that one element in the effectiveness of HCT is due to disruption of an ongoing immune response, and that antigen exposure at the time of the procedure (and not before) is required for shifting the response from immunogenic to tolerogenic.

The positive results from syngeneic BMT were repeated in a genuine autologous transplantation study wherein BM was harvested from arthritic rats by surgical removal of a femur, followed by preparation with myeloablative radiation and intravenous return of their own BM cells [145]. Thereafter, in order to reduce the suffering of the affected animals, transplantations were performed using pseudoautologous donors with the same stage of disease severity as the recipients at the time of transplantation.

The curative effect of syngeneic and pseudoautologous BM transplantation was confirmed by van Bekkum and colleagues in a different AD rat model – EAE [120,146,147]. Myeloablative radiation (850–1000cGy) administered shortly after the appearance of clinical symptoms induced a transient exacerbation of disease but most rats achieved remission from EAE following transplantation of syngeneic BM [147]. That said, a certain percentage of these animals spontaneously relapsed. Less intensive conditioning with a non-ablative dose of 750cGy total body irradiation (TBI) plus CY also resulted in complete remission in many rats, but the rate of spontaneous relapse was much higher than that observed with the myeloablative treatment. Hence EAE appeared to be more resistant to the curative effects of syngeneic BMT compared with adjuvant induced arthritis.

Success using syngeneic BMT in treating a different rodent genus, mice, with EAE or spontaneously arising SLE (MRL-*lpr/lpr*) was also demonstrated by Karussis and colleagues [94,148,149]. Their EAE studies [94,150] tested recipient conditioning in early-stage disease with two doses of myeloablative radiation (900 vs. 1100 cGy) or single-dose CY (300 mg/kg). Recipient preparation with CY yielded slightly better results than 1100 cGy of radiation, and both of these treatments proved significantly better than with 900 cGy. The inclusion of CY as a conditioning agent by this group and others was highly clinically relevant given the widespread use of CY in the treatment of human ADs, and its use was based on several earlier reports demonstrating the efficacy of CY alone in the treatment of rodent ADs [121–123]. Mice treated with either TBI or CY plus syngeneic BMT were resistant to disease relapse when rechallenged with the encephalitogenic inoculum, leading to the conclusion that immunoablation followed by reconstitution induces immune tolerance to the autoantigen. The effect of high-dose CY without syngeneic BM rescue [150] was also tested. Although disease symptoms were ameliorated, survival was inferior compared with the BMT groups, suggesting that early rescue of hematopoietic function optimized the therapeutic outcome. Of note, mice that had paralysis for 14 days or greater experienced only a mild therapeutic effect. These investigators extended their studies on syngeneic BMT to the SLE-prone MRL-*lpr/lpr* mice (a spontaneously arising disease) [149]. Preparation with either lethal TBI or high-dose CY and rescue with TCD or unmanipulated syngeneic BM resulted in improved survival and amelioration of serologic and pathologic evidence of disease in all treatment groups, unlike untreated controls. However, long-term follow-up at >20 weeks post-transplantation revealed a significant incidence of relapse. Under both preparative regimens, recipients of TCD BM grafts produced superior results to unmanipulated BM.

Autologous HCT in different disease phases

The early studies suggested that the timing of HCT relative to disease phase is critical to the success of the procedure. Since it is expected that only patients with severe and long-standing ADs will be candidates for HCT, the relevance of timing to clinical translation prompted studies comparing HCT at early and late time points relative to disease induction. Most reports have focused on EAE. Burt et al. [151] showed in a mouse model of EAE of adoptive lymphocyte transfer that clinical improvement and prevention of glial scarring were achieved by syngeneic BMT if mice were treated in the acute but not the chronic phase (day +14 versus day +75 post-lymphocyte transfer, respectively). Herrmann et al. [144] observed that disease symptoms in rats affected with MOG-induced EAE could be attenuated by transplantations from syngeneic, pseudoautologous, and allogeneic donors if rats were treated at the peak of acute disease after immunization (day +17) but not when the disease was in a chronic phase (day +140). Cassiani-Ingoni et al. [152] tracked green fluorescence protein (GFP)-marked congenic BM cells in the CNS of EAE-affected mice that were irradiated and infused with these cells early in the disease or during the chronic phase. In agreement with other reports, transplantation was more effective when performed in the early stage of disease. However, changes in the peripheral immune system, that is, reconstitution by donor elements, did not influence host glial cell inflammatory responses to injury in the CNS which appeared to perpetuate the disease process. Their results suggest that the pathophysiology of an AD occurring within a target tissue may evolve over time such that even aggressive modulation of lymphoid responses will be insufficient to interrupt the process of tissue injury.

Failures of autologous HCT: does T-cell depletion improve the outcome?

Why some animal ADs respond to syngeneic HCT whereas others do not is a subject of debate. One hypothesis for the discrepancies is that antigen-induced diseases are more amenable to treatment with autologous HCT than the spontaneously arising diseases. Indeed, all of the reports showing successful long-term “cures” with syngeneic HCT have been in animals with antigen-induced diseases. van Bekkum [7] suggested that antigen-induced ADs are the more realistic models of human disease, since their etiology seems to resemble more closely events proposed to induce disease in human counterparts, such as exposure to antigens cross-reactive to normal tissues. Although this point is not proved, the successes described above have paved the way to the establishment of large clinical trials testing the use of autologous HCT for the treatment of severe and refractory human ADs [103,109–111] (see Chapter 67).

One possible reason why spontaneously arising diseases did not respond to syngeneic BMT is because preformed autoreactive cells were not completely removed from the grafts. Indeed, syngeneic BMTs in the spontaneously arising lupus and MRL-*lpr/lpr* model showed better outcomes in recipients of TCD versus non-TCD BM [149]. Results were also different in an antigen-induced rat EAE model wherein comparisons were made between pseudoautologous, syngeneic, and TCD BM. Significantly higher incidences of spontaneous relapse were observed in rats that received BM plus peripheral lymphoid cells from pseudoautologous donors [146]. Given the newer technologies that permit the isolation of highly purified KTLS HSCs devoid of T-cell contamination, and the capability to deplete endogenous host T cells more rigorously with mAb targeting, studies have been carried out to re-evaluate whether with such maneuvers syngeneic HCT might be more successful in treating spontaneously autoimmune mice. In experiments by Beilhack et al. [129], prediabetic NOD mice prepared for transplant with myeloablative radiation and anti-T-cell antibodies were rescued with grafts composed of purified KTLS cells plus marked T cells from standard NOD mice and Thy-1.1 congenic NOD mice, respectively. Despite this treatment, most mice developed hyperglycemia within 6 months post-transplant. In the same study, KTLS allogeneic HSCs blocked diabetes development in 100% of mice (Figure 18.3). Similarly, syngeneic KTLS HSC transplantations failed to alter disease manifestations in lupus-prone (NZB×NXW) F_1 mice conditioned with high-dose (1450 cGy) radiation [135], whereas haplo-identical HSC grafts resulted in significant resolution of lupus parameters and prolonged survival. Thus, aggressive myelo- and lymphoablation and rescue with genetically identical grafts devoid of mature lymphoid cells were insufficient to block autoimmunity in at least two of the models of spontaneous AD. Although these data seem to support the idea that autoimmunity arises as a result of "defective stem cells," as discussed earlier in this chapter, autoimmunity in animals such as NOD and (NZB×NXW) F_1 mice is based upon multiple genetic defects that reside both within the hematopoietic lineage and outside.

Autologous transplantation augmented by gene therapy

The intent of autologous HCT to treat ADs is to eliminate disease-causing cells and establish a new immune repertoire devoid of activated pathogenic cells. This "conventional" approach involves the regeneration of a hematolymphoid system that follows a genetically scripted program driven by stochastic events encountered in the environment. Thus, the desired outcome of an immunologic "reset" to alleviate or cure disease is partly left to chance. Because experimental biologists can routinely produce genetically altered cell lines, the idea has emerged that BM can be engineered to express molecules capable of tipping the balance towards immune tolerance following transplantation. Several laboratories have reported success in blocking autoimmune pathology by the expression of selected "protective" molecules in hematolymphoid cells and transplantation into autoimmune-susceptible or -affected hosts [153,154]. Enforced expression of auto- or neoantigens by APCs has been pursued based on the known importance of APCs in inducing and maintaining central and peripheral tolerance. In that regard, expression targeted via the MHC class II promoter has allowed molecules known to be major targets in specific ADs to be expressed on APCs. Murphy et al. [155] used a double-transgenic model of autoimmune gastritis to demonstrate that transfer of BM from disease-resistant transgenic mice that express a gastric antigen (H/K/ATPase) driven by an MHC class II promoter into mice that develop gastritis due to expression of the pro-inflammatory granulocyte–macrophage colony-stimulating factor (GM-CSF) established tolerance to the antigen. Steptoe et al. [156] tested a similar strategy in NOD mice. Proinsulin, the prohormonal precursor of insulin, is implicated as a key autoantigen that drives β-cell destruction in humans and mice. NOD transgenic mice were generated that expressed proinsulin under the control of an MHC class II promoter. Transplantation of these transgenic hematopoietic cells significantly inhibited the development of diabetes in prediabetic NOD mice [156].

Proof of concept that this type of gene therapy can be performed in humans was demonstrated by transplantation of syngeneic cells that were retrovirally transduced ex vivo with autoantigens rather than harvested from transgenic donors. In one study, proinsulin-transduced BM inhibited insulitis in NOD recipients [157], and in another MOG-transduced cells both protected mice against EAE development and interrupted disease progression [158]. Although promising, this approach is applicable only to ADs in which a major offending antigen is known (so that tolerance develops specifically to the autoantigen), which for most human ADs is generally not the case; and the same constraints regarding the timing of transplant relative to end organ damage apply to such gene-manipulated cells. Furthermore, consistent with the idea that intensive immune ablation is required for optimal therapy from autologous HCT, transplants of autoantigen-expressing cells into non-myeloablated recipients have been less efficacious that myeloablative approaches.

Given the known role of disease susceptibility MHC class II alleles, the class II molecule itself has been a target for genetic manipulation (Figure 18.5). NOD mice express a single MHC class II molecule that is strongly associated with disease susceptibility (I-A^{g7}). Tian et al. [159] performed retroviral transduction of NOD BM cells with non-susceptible I-$A\beta^{d}$–GFP or I-$A\beta^{k}$–GFP constructs. Expression of either of these retrovirally encoded MHC class II genes in NOD BM prevented islet inflammation and hyperglycemia when transplanted into young irradiated NOD mice. They also showed that the MHC class II–GFP-transduced BM cells could protect against recurrent autoimmunity against islets, since overtly hyperglycemic NOD mice could be cured of their disease if transplanted with transduced BM plus NOD–SCID islets, whereas controls that received GFP-transduced BM plus islets quickly destroyed their islets [160]. It is worth remembering, however, that MHC class II gene products are histocompatibility antigens. Therefore, for the purposes of gene therapy and transplantation of the modified cells, expression of these molecules can result in untoward effects such as increased engraftment resistance and even potentially chronic GVHD [30,161].

Another related area of exploration is adoptive immunotherapy, which targets gene expression to cells of specific hematolymphoid lineages. Primary T cells, Tregs, T-cell hybridomas, B cells, and DCs have been tested [162]. When transduced with regulatory proteins such as IL-4, IL-10, anti-TNF, and others, these populations have been shown to home preferentially to sites of inflammation and ameliorate disease in autoimmune animal models. Although this form of cellular therapy has proven efficacy in vivo, its effectiveness would likely be potentiated in the context of autologous HCT. Autologous HCT results in significant cytoreduction of pathogenic cells and provides a host environment that could promote greater expansion of gene-modified populations (e.g. via mechanisms of homeostatic proliferation) compared with unconditioned recipients.

Allogeneic HCT

In contrast to the conflicting preclinical literature supporting the use of autologous HCT for ADs, several studies have demonstrated that both spontaneous and induced forms of rodent ADs can be successfully treated by allogeneic HCT [7–9]. Indeed, the seminal studies by Morton and Siegel (Figure 18.3) showing success with allogeneic but not syngeneic BMT [5] motivated this area of research. Variability exists among the experiments, including the

Figure 18.5 Strategy to overcome T1DM in NOD mice by genetic engineering of hematopoietic stem cells (HSCs). Retroviruses carrying MHC class II β chain genes from protective haplotypes are cloned into retroviral vectors. The produced recombinant viruses are then used to deliver the genes to NOD mouse HSCs which are then transplanted into conditioned NOD mice. The product of the protective β chain gene competes for the endogenous α chain to reach the cell surface of MHC class II positive cells, restoring expression of non-autoimmune, wild-type MHC class II molecules on the cell surface. Expression of these restored molecules prevents development of T cells that cause diabetes. Source: Tian et al. 2009 (http://www.discoverymedicine.com/Chaorui-Tian/2009/07/24/preventing-autoimmune-diabetes-through-gene-therapy/). Copyright 2014 Discovery Medicine. All rights reserved.

models tested, degree of donor/host genetic disparity, measurements of donor chimerism outcome, the hematopoietic graft type, the preparative regimens, and timing of the HCT procedure relative to the onset of disease manifestations. Given these heterogeneities, it is therefore striking that rodents are consistently cured by an allogeneic HCT approach.

Treatment of spontaneous ADs with allogeneic HCT

In 1985, Ikehara and Good began a large series of studies demonstrating that allogeneic BMT could successfully treat spontaneously arising ADs in affected mice with overt clinical symptoms [8,9]. Similar to earlier reports, mice with spontaneously arising SLE-like syndromes were transplanted, including MRL-*lpr/lpr* (NZB×NBW) F_1 and BXSB strain mice [163,164]. Resolution of symptoms was achieved even though treatment was initiated at relatively advanced stages of disease. They went on to show protection from progressive insulitis and development of diabetes in young NOD mice [165]. Mice in their studies were prepared for transplantation with lethal (myeloablative) radiation and in the initial reports recipients were rescued with either TCD BM from wild-type mice or BM from mice with the *nu/nu* defect. Thus, mature T cells were not transferred, but grafts gave rise to functional T cells. Such grafts were incapable of causing GVHD, but were also limited in their ability to eliminate host T cells. Most of the experiments were performed between MHC-mismatched donor–recipient pairs. Donor chimerism was evaluated by H-2-specific antisera plus complement assays, and uniformly revealed that >90% of spleen cells were of donor type. With the exception of the MRL-*lpr/lpr* SLE-affected mice [106] and NZB/KN mice that develop a spontaneous inflammatory polyarthritis [105], such allogeneic HCT was uniformly successful not only at blocking disease progression, but also in resolving already established inflammatory lesions [163].

Competitive advantage of autoimmune HSC?

The reasons why allogeneic BMT was unsuccessful in the MRL-*lpr/lpr* and NZB/KN mice were further studied by Ikehara and colleagues [105,106]. In these strains, HCT resulted in initial reversal of clinical manifestations and restoration of other immune aberrations; however, the effects of the transplants were transient and mice regularly relapsed [163]. H-2 typing of the relapsed mice revealed correlation with the return of symptoms and loss of donor chimerism. These graft failures were attributed to abnormal radioresistant HSCs in the autoimmune host strains. An additional competitive advantage of HSCs from MRL-*lpr/lpr* mice was linked to enhanced adhesion to stromal cells. MRL-*lpr/lpr* mice express high levels of the neural cell adhesion molecule (NCAM) [166], which supports hematopoiesis on stromal cell lines [167]. Successful engraftment of MHC-mismatched BM and long-term disease-free survival were achieved in both MRL-*lpr/lpr* and arthritic NZB/KN models [105] by intensifying the conditioning regimens and placement of donor bone grafts [106]. The rationale for the added bone grafting was based upon the investigator's earlier studies, which showed better colonization and proliferation of donor BM on H-2-matched bone grafts [8], consistent with the idea that H-2-compatible BM stroma facilitates enhanced hematopoietic cell engraftment.

Studies characterizing hematopoietic transplantations in spontaneously diabetic NOD mice similarly suggested that HSC/progenitors from this disease-prone strain exhibit enhanced engraftment potential compared with those derived from disease-resistant strains [168]. NOD progenitors exhibited a competitive advantage when co-administered with host-type HSCs in irradiated recipients. They also produced more spleen colony-forming units (CFU-Ss) in vivo in allogeneic recipients and more granulocyte–macrophage colony-forming units (CFU-GMs) in vitro compared with at least four disease-resistant control strains. Enhanced chemotaxis to stromal cell-derived factor 1 (SDF-1) and adherence to BM stroma were proposed as potential mechanisms that permitted a superior NOD HSC engraftment.

The observations that HSCs from certain autoimmune-prone strains dominate hematopoiesis are relevant to the translation of the allogeneic HCT approach to the treatment of human ADs. If HSCs in AD-affected individuals do indeed have a competitive advantage, then designing the appropriate conditioning regimens and graft content that will permit permanent donor cell chimerism will be all the more challenging. However, it is yet to be definitely proven whether or not HSC engraftment potential and autoimmunity are linked. It is known that among non-AD-prone strains, differences exist in the cell autonomous behavior of HSC [169–171]. Hence it is possible that the observations made in the MRL-*lpr*/*lpr*, NZB/KN, and NOD mice are reflective of HSC characteristics that are separate from autoimmunity.

Transplantation of purified HSCs

Reports in the NOD diabetes [129,136] and lupus-prone (NZB×NXW)F_1 models [135] (described above) demonstrated that AD in genetically prone mice was not altered by myelo- and lymphoablation and rescue with purified syngeneic or congenic HSCs. However, in the same studies, engraftment of allogeneic KTLS HSCs successfully blocked autoimmune pathogenesis. Beilhack and co-workers [129,136] showed in prediabetic NOD mice that engraftment of either purified MHC-mismatched HSCs or BM conferred equal protection and resolution of islet inflammation. Of note, the pattern of blood chimerism differed significantly between these groups. NOD mice transplanted with purified HSCs remained mixed T-cell chimeras for an extended period of time post-transplantation, whereas BM-transplanted animals converted promptly to complete donor T-cell type. In both groups, the other blood lineages (B cells, macrophages, granulocytes) were 100% donor derived. The significance of persistent host T cells in animals with spontaneously arising ADs is that these host cells have the potential for autoreactivity (discussed in detail in the later section Mechanisms by which allogeneic HCT abrogates autoreactivity). Smith-Berdan et al. [135] made similar observations when transplanting haplo-identical KTLS HSCs in (NZB×NXW)F_1 lupus-prone mice. Stabilization or reversal of lupus signs was achieved and recipients were mixed T-cell chimeras, whereas the B-cell and myeloid compartments were donor derived. Together, these data provide evidence that allogeneic HSCs alone give rise to elements capable of modifying the activity of radiation resistant autoreactive cells and that complete replacement of donor T cells is not a requirement to obtain curative benefit from allogeneic HSC transplantation.

Allogeneic HCT and antigen-induced ADs

Genotype and susceptibility

The important distinction between induced ADs and spontaneous ADs is that the latter generally arise in the context of a genetic background with multiple immune defects, whereas the former are induced in wild-type animals and require purposeful immunization to break T-cell tolerance. Nonetheless, susceptibility to develop an induced AD also appears to be strain specific since it is observed that for any given antigen immunization protocol, certain rodent strains are more likely to develop autoimmunity whereas others are resistant. Similarly to the spontaneously arising ADs, much of the early literature on BM transfer experiments in autoantigen-immunized rodents sought to identify the cellular elements controlling autoreactivity. Hence the studies were not designed to examine the curative potential of BMT that would involve BMT after disease induction – rather, they focused on the induction of disease in already established radiation BM chimeras. In agreement with the studies in spontaneously arising ADs, the BM genotype seemed to dictate disease susceptibility or resistance [7]. Furthermore, there were at least two independent reports in 1981 [172,173] in which the authors surmised that the mechanism by which the BM genotype exerts its autoreactive or protective effects is at the level of antigen presentation to T cells – a hypothesis that remains compelling, although yet to be proved.

A notable exception to the results demonstrating that BM genotype is the sole determinant of induced AD development was published by Korngold et al. [142] in a model of EAE. In that study, reciprocal transplantations were performed between MHC-matched strain mice that were either highly responsive to mouse spinal cord homogenate (MSCH) (SJL) or low responders (B10.S). Challenge of chimeras with MSCH derived from SJL spinal cord led to a high incidence of disease in the B10.S into SJL chimeras, but not in the SJL into B10.S mice, demonstrating that the BM from the low responders did not protect the recipients. The outcome differed if chimeric mice were immunized with MSCH derived from B10.S mice in that both B10.S into SJL and SJL into B10.S chimeras developed severe disease. These data suggested that non-hematopoietic factors, such as elements within the CNS, control the EAE development. The same group published a separate study in a relapsing EAE model [141]. These experiments showed that immunization with MSCH derived from third-party MHC-disparate BALB/c or B10.S mice resulted in disease in B10.S into SJL chimeras but not SJL into B10.S chimeras, indicating once again that restriction in the development of EAE involves elements outside the hematopoietic system.

Treatment of induced ADs with allogeneic HCT

Success in curing advanced-stage induced ADs with allogeneic HCT was reported beginning in the late 1980s. van Bekkum and co-workers established the adjuvant-induced arthritis and EAE models in rats and tested the efficacy of MHC-mismatched transplantation in conjunction with the autologous HCT studies described above [7]. It was in the adjuvant arthritis model that equivalence in the effect of syngeneic as compared with allogeneic BMT was first described (Figure 18.5) [143]. Susceptible rats were lethally irradiated and received either BM from non-susceptible MHC-mismatched rats or syngeneic BM at weeks or many months following immunization with the adjuvant (*Mycobacterium tuberculosis*). The most effective results were obtained when treatment was initiated shortly after evidence of clinical manifestations at 4–7 weeks post-immunization. Rats treated at the later stage had limited recovery with stabilization of disease, but not complete regression.

Equivalent responses were seen in disease-affected recipients of allogeneic or syngeneic BM.

Comparative studies of syngeneic versus MHC-mismatched allogeneic BMT have been performed in the rat EAE model [120,144]. In 1995, van Gelder and van Bekkum performed transplantations in the rat spinal cord homogenate (RSCH) plus adjuvant model comparing syngeneic grafts with TCD BM or BM from TCD *nude* rats [120]. Syngeneic transplantation was initially effective in inducing remissions in all recipients. However, as discussed earlier, these results differed from those in the adjuvant-induced arthritis studies, since syngeneic and pseudoautologous recipients demonstrated significantly increased incidences of relapse that occurred spontaneously or following rechallenge with the spinal cord antigen. In contrast, all allografted rats had complete remissions with markedly reduced spontaneous and induced relapses. The superior outcome of allogeneic HCT was attributed to a subclinical graft-versus-host reaction (which would later be termed GVA). The rat EAE studies were extended to the use of MHC-matched donors [174]. Again, recipients of allogeneic BM were observed to induce complete remissions with low relapse rates compared with pseudoautologous recipients. Mixed chimeric recipients were created by using grafts of TCD syngeneic plus TCD allogeneic BM. These mixed chimeras relapsed more frequently than the complete chimeras, leading the investigators to conclude that clinical protocols for the treatment of multiple sclerosis should be designed to achieve full donor chimerism. The issue of whether or not a major goal of clinical allogeneic HCT for ADs should be mixed or full donor chimerism is still an open question. Subsequent animal studies that tested reduced-intensity preparative regimens (see the following section) have resulted in numerous reports demonstrating that mixed hematopoietic cell chimerism results in successful amelioration of disease.

Herrmann et al. [144] reproduced and extended the observations made in the rat EAE model. MHC-matched and also syngeneic BM transplantations conferred significant clinical improvement in MOG-immunized EAE-affected rats. In agreement with other reports, HCT was effective in the acute but not the later phase of disease, and in the later phase allogeneic transplantation was no better than syngeneic. Rats transplanted during the peak of EAE disease and that improved were protected from relapse when challenged again with the original MOG immunogen, but not when a different epitope of MOG was used for the rechallenge, a finding that supports the idea that HCT induces antigen-specific tolerance. Furthermore, disease protection correlated with the presence of increased numbers of $CD4^{+}CD25^{+}FoxP3^{+}$ cells. Van Wijmeersch et al. [175] also studied amelioration of EAE in affected mice that underwent allogeneic HCT from susceptible versus non-susceptible donors. Their data indicated that high levels of donor chimerism from a non-susceptible donor were required to achieve the best therapeutic effect. Furthermore, alloreactivity induced by donor lymphocyte infusions (DLIs) enhanced the protective effect, thus supporting the idea that strong GVA is important for effectively treating ADs.

MHC-mismatched versus matched HCT

Most preclinical studies that have tested the efficacy of allogeneic HCT on AD pathogenesis utilized grafts mismatched at both MHC and minor histocompatibility loci. Surprisingly few have used transplantations of MHC-matched hematopoietic cells [4,131,136,174]. The importance of MHC identity or non-identity relates both to the direct translation of the animal data to clinical protocols as ideally HLA-matched donors will be used, and to the mechanism by which allogeneic HCT mediates its AD protective effect. Given the well-known association of MHC-genotype with autoimmunity (Table 18.1) and the importance of MHC molecules in shaping and maintaining the T-cell repertoire, the effect of MHC-matched transplantation on AD recipients should be a central issue. As a generalizable principle, it might be expected that donor grafts mismatched at the MHC would be more effective in blocking autoimmune pathogenesis than grafts that are MHC-matched.

In 2005 Beilhack et al. [136] and in 2011 Racine et al. [176] examined the effect of MHC-matched HCT in rodent disease with the strongest MHC association, namely diabetes in NOD mice. Disease development in NOD mice has a well-known linkage to the expression of a single unique class II MHC molecule, designated I-A^{g7}. In fact, NOD disease susceptibility appears to depend upon the presence of the I-A^{g7} molecule. Transgene expression of non-I-A^{g7} in the germline of NOD mice and also transplantation of transgenic BM expressing non-susceptibility class II alleles into young NOD mice result in protection against the development of hyperglycemia [159,177]. B6.H-2^{g7} mice that were C57BL/6 strain but congenic for the entire NOD MHC region and disparate at minor histocompatibility loci were used as donors of BM or purified KTLS HSC [136]. Transplantation of either graft type into myeloablated prediabetic NOD recipients resulted in 100% protection against diabetes. Because of the rigorous T-cell depletion, KTLS HSC recipients were partial T-cell chimeras with significant residual NOD host T cells remaining. These data give confidence that HLA-matched donor HCTs can be effective in the treatment of human ADs, since non-MHC "background" genes conferred protection even in the presence of a strong disease-linked MHC allele. Of course, a next important step is to identify and characterize the protective non-MHC genes.

Reduced-intensity allogeneic HCT and establishment of mixed chimerism

The major limiting factor in treating human ADs with allogeneic HCT is concern about the morbidity and mortality of the transplant procedure. Two ways in which the dangers of the procedure can be significantly decreased are by reduced-intensity conditioning (RIC) and reduction of donor T cells to remove the risk of GVHD. By performing these kinds of maneuvers, the expectations are that recipients will develop mixed donor–host chimerism rather than convert to complete donor type. The establishment of mixed donor chimerism has not been an end-goal for clinical transplantations, since the majority of HCTs are done for hematolymphoid malignancies and graft-versus-tumor (GVT) responses with conversion to donor type are thought to be an essential element in the therapy. However, for ADs where GVT is not needed, the question remains, will the establishment of mixed chimerism be sufficient to block autoimmunity? The prevalence of RIC protocols in the human HCT literature is in no way matched by animal studies. There are relatively few preclinical reports on the topic of RIC transplantation for the treatment of ADs.

Li et al. [178] demonstrated that disease in NOD mice could be successfully blocked with reduced doses of radiation when delivered in conjunction with infusion of high amounts of MHC-mismatched unmanipulated BM, and that despite the lower dose radiation, the high BM dose resulted in high levels of donor chimerism (>95%). Mixed chimeric NOD recipients and disease protection were also shown by treatment with lethal radiation and rescue with grafts that contained both NOD plus donor cells

[179,180]. Beilhack et al., showed that stable multilineage chimerism and prevention of diabetes in NOD mice could be more readily achieved using MHC-matched (B6.H-2^{g7}) purified HSC grafts [136]. These latter studies addressed the clinical question raised above, as it was shown that reduced-intensity treatment and the establishment of "true" mixed chimerism using grafts that were rigorously depleted of T cells and from MHC-matched donors were curative of this AD (Figure 18.6). Liang et al. [127] generated MHC-mismatched mixed chimeras in NOD mice using a novel non-radiation-based regimen of anti-CD3 antibody and grafts composed of high-dose MHC-mismatched BM plus CD8$^+$ T cells. Islet destruction was blocked [127] and even reversed in newly diabetic NOD mice [181], suggesting that effective disruption of the autoimmune process by allogeneic HCT in new-onset diabetics in whom some islet mass is preserved (a period in humans with T1DM termed the "honeymoon" phase) may prevent or delay the need for exogenous insulin. However, in contrast to the earlier studies by Beilhack et al. [136] when this same regimen was used to generate MHC-matched partial chimeras, recipients were not protected from diabetes development. These conflicting studies using MHC-matched grafts suggest that the mere establishment of mixed allogeneic chimerism may not be sufficient for protection from autoreactivity, but rather in addition, the method of conditioning as well as graft content will impact the outcome.

Proof that both non-myeloablative regimens and allogeneic HCT can induce tolerance to autoantigens and alloantigens has been shown by studies that combine both HCT and islet transplantation to cure overtly diabetic NOD. Seung et al. [128] used a preparative regimen of sublethal radiation plus anti-CD40 ligand (CD40L) mAb that resulted in high levels of MHC-mismatched donor chimerism (>99%) in most mice. Diabetic chimeric NOD mice were transplanted with donor-matched islets and achieved long-term normoglycemia. Sykes and colleagues [130] employed a conditioning regimen that combined anti-CD4, anti-CD8, anti-Thy-1.2, and anti-CD40L mAbs plus low-dose radiation [400cGy) to achieve engraftment of MHC-mismatched BM in

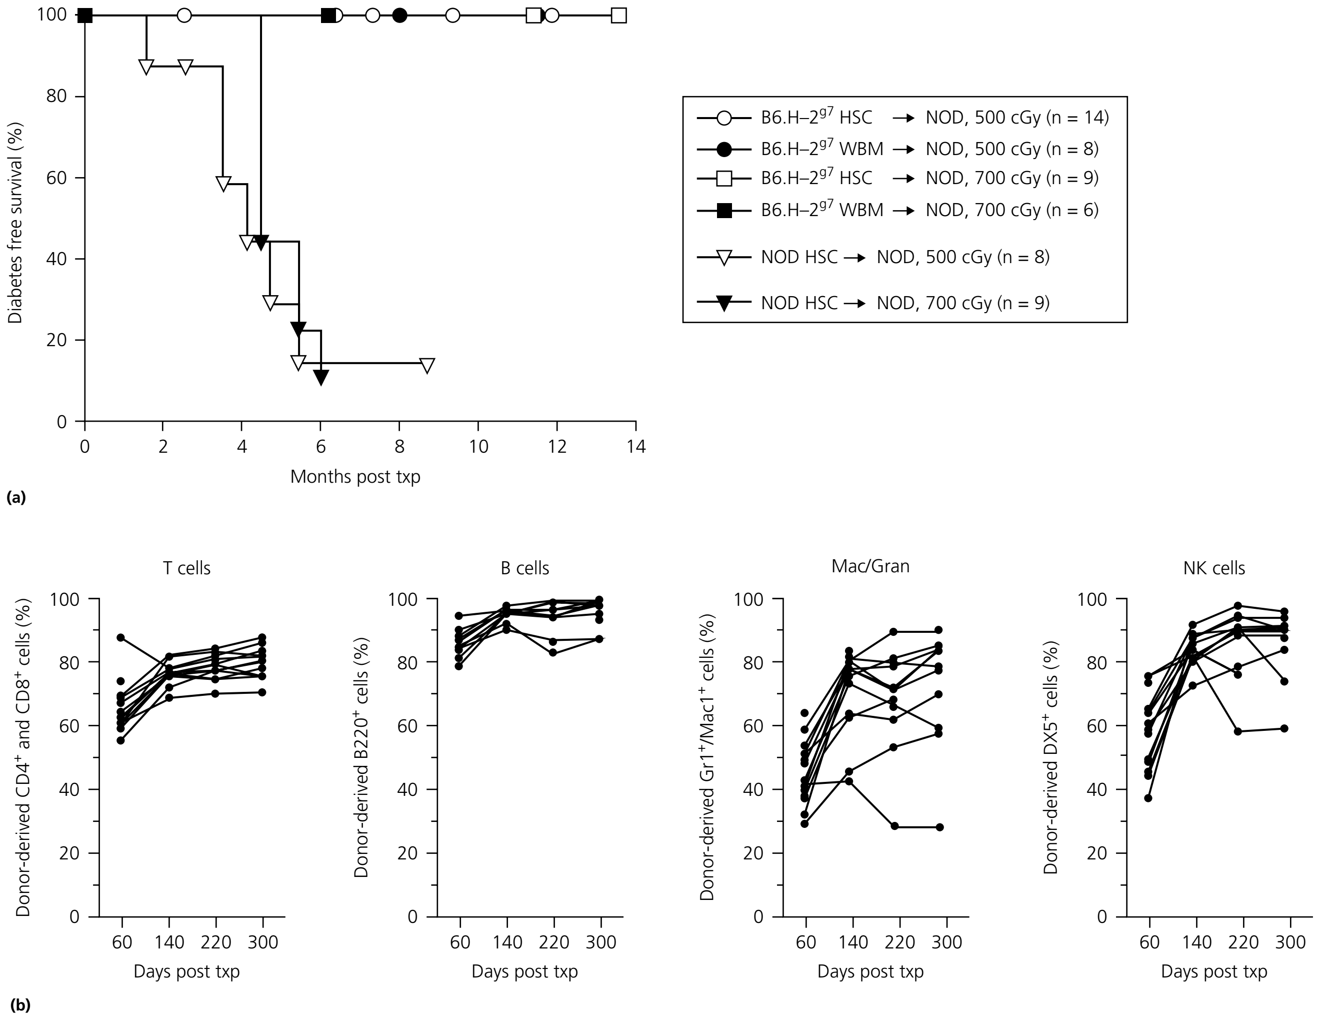

Figure 18.6 Non-myeloablative transplantation of MHC-matched hematopoietic stem cells (HSCs) results in multilineage chimerism and blocks autoimmunity. (a) Prediabetic NOD mice were prepared for transplantation with sublethal radiation (500 and 700 cGy) which was sufficient to permit engraftment of MHC-matched purified HSCs from B6.H-2^{g7} donors. Recipients of B6.H-2^{g7} HSCs or whole bone marrow (WBM) were protected from diabetes development. Recipients similarly prepared and transplanted with syngeneic HSCs progressed to hyperglycemia. (b) Testing of blood revealed the non-myeloablated NOD recipients to be stable mixed chimeras. Shown are the chimerism studies for the different blood cell lineages from NOD mice that received 500 cGy and B6.H-2^{g7} HSCs and that were followed up to 1 year post-transplantation. The mixed granulocyte–monocyte lineage demonstrates that these recipients had continued hematopoiesis from host HSC.

overtly diabetic NOD mice. Multilineage chimerism was established with amelioration of autoimmunity and the induction of tolerance to donor-matched islets.

In other non-diabetic autoimmunity models, reduced-intensity conditioning with allogeneic HCT has been shown to halt disease pathogenesis. Flierman et al. [182] showed efficacy in the collagen-induced arthritis model using sublethal radiation conditioning plus anti-CD40L and MHC-mismatched donors. Interestingly, both syngeneic and allogeneic BMT led to clinical suppression of arthritis, although allografted mice demonstrated superior reduction of pathogenic antibodies. Smith-Berdan et al. [135] achieved durable multilineage mixed chimerism following transplantation of haplo-identical KTLS HSCs in radiation-resistant SLE-prone (NZB×NZW)F_1. These stable chimeras had superior survival and exhibited stabilization or reversal of their lupus symptoms, which included proteinuria, circulating immune complexes or autoantibodies, compared with untreated controls and syngeneic recipients.

In summary, many animal studies using reduced-intensity conditioning have been consistently successful in blocking autoimmune pathology, even when significant levels of potentially autoreactive host cells persist. That said, the majority of the proof that mixed chimerism is sufficient to block autoimmunity comes from transplantations of MHC-mismatched grafts. When the anti-host immune effect of the allograft is weaker, as in the case of MHC-matched transplants, we expect that the type of conditioning and graft type will play a more prominent role in whether or not the procedure is a success.

Mechanisms by which allogeneic HCT abrogates autoreactivity

The way in which allogeneic HCT interrupts AD pathogenesis is by a combination of mechanisms that extend beyond the standard activities required for treatment of malignancies. Similar to transplants for cancer, conditioning regimens provide cytoreduction of pathogenic host immune cells, and donor allografts that contain T cells can also reduce host T cells and other immune cell populations, an effect referred to as graft-versus-autoimmunity (GVA). In addition, within the autoimmune-prone host, the allograft establishes its own immune system capable of generating cells that can control immunity and that follow the genetic programming of the donor. The superior outcomes in allogeneic animal models that result in mixed chimeras compared with syngeneic models underscores this latter point. Autologous HCT succeeds because of the stochastic interactions that occur between a regenerating immune system and non-hematopoietic factors that determine restoration of self-tolerance. It is thought that allogeneic HCT demonstrates higher success rates because in the process of regenerating immunity certain susceptibility genes expressed on host hematopoietic cells are either replaced or differentially expressed by the donor. These expressed gene products impact on the pathways of central and/or peripheral tolerance favoring a protective outcome.

T-cell depletion

Depletion of host T cells is the most extensively studied mechanism by which allogeneic HCT can alter immune function. There is ongoing discussion amongst clinical transplant professionals regarding the need to achieve full donor T-cell chimerism in order to obtain cures of human ADs. Separate from the effects of conditioning, unmanipulated allogeneic hematopoietic grafts replete with mature immune elements have the capacity to eliminate or reduce residual host hematolymphoid elements. GVA is the term that describes this pan-alloreactivity and conversion to complete donor type serves as a surrogate marker for GVA activity. Although elimination of host T cells by this mechanism certainly increases the likelihood that autoreactivity will be reduced, GVA will be accompanied by significantly increased risk of GVHD. Of note, GVHD is in and of itself immune suppressive because lymphoid organs are major targets of alloreactive T cells. Even low levels of mature donor T cells can result in a syndrome of subclinical GVHD wherein immune responses are impaired [183]. Therefore, attention should be paid as to whether or not autoreactivity is blocked because of globally impaired function versus more specific alterations in immunity.

Many of the animal studies on the topic of HCT for the treatment of ADs predate the technologies that allowed the measurement of donor-versus-host hematopoiesis. Hence T-cell chimerism was not assessed and it was assumed that animals surviving lethal radiation and BMT converted to donor type. Indeed, later studies by Ikehara et al., in which chimerism of the blood or spleen was assessed, showed chimerism levels of >90% [163] although lineage subset analyses were not performed. From more recent reports using purified HSCs [129,135,136,138], clinical studies examining chimerism in patients of TCD grafts [184], and analyses of chimerism following RIC transplantation [185], it is evident that the T-cell lineage is the most resistant to conversion to donor type. HSCs and TCD BM lack or have reduced amounts of alloreactive GVA populations that mediate elimination of residual host immune cells [137,138]. Transplantation of allogeneic unfractionated BM into lethally irradiated mice results in near complete conversion to donor type, whereas HSC transplantations result in persistent partial T-cell chimerism [138,186]. Patients who have received TCD BM also demonstrate long-term mixed chimerism [184,187,188]. It is therefore reasonable to conclude that in the many preclinical experiments wherein T-cell chimerism was not assessed, but in which TCD or BM from *nude* mice was used as the graft source, those autoimmune affected recipients remained as partial T-cell chimeras.

Central and peripheral T-cell deletion

Beyond T-cell depletion by conditioning or overt alloreactivity, potentially autoreactive T cells can be eliminated by negative selection. Negative selection, a fundamental mechanism by which the immune system maintains T-cell tolerance, occurs by both central thymic deletion, and peripheral deletion of post-thymic cells [189]. BM-derived APCs are the most efficient mediators of negative selection. In a non-transgenic animal, it is virtually impossible to demonstrate directly negative selection of T cells for any particular self-antigen because, generally, antigen-specific T cells are too few in number to detect. One way to follow the fate of an antigen-specific T cell in experimental models is to utilize TCR transgenic mice that have high levels of a single clone which can be identified by reagents such as a labeled MHC tetramer plus peptide known to bind the transgenic T cells. Racine et al. [176] used this approach to show that hematopoietic allografts could mediate thymic deletion of autoreactive T cells in TCR-transgenic NOD mice that have high levels of an anti-islet T-cell clone. In this study, MHC-mismatched but not MHC-matched hematopoietic grafts were capable of deleting the anti-islet clone.

Another method to track T-cell deletion is via methods that follow responses to a class of non-conventional antigens called superantigens [190]. Superantigens are viral or bacterial proteins that interact with T cells via the class II MHC and Vβ segment of the TCR. T cells bearing the Vβ segment specific for the antigen die by apoptosis, resulting in nearly complete elimination of all cells of the responding Vβ subclass. Some superantigens exist as endogenous genes in mice of certain strains, and during T-cell development the cells with receptors that have the Vβ capable of reacting to these “self antigens” are deleted by negative selection. Hence tracking T cells based upon Vβ staining in experimental systems in which exposure to superantigens can be manipulated (such as BM chimeras) serves as a surrogate assay for assessing negative selection. Using the superantigen system, Beilhack et al. [129] demonstrated the ability of purified HSC allografts to mediate negative selection of T cells reactive to endogenous superantigens by measuring Vβ subsets in chimeric NOD mice transplanted HSCs from donors that differed in superantigen expression. Such mixed chimeric NOD mice had significant residual T cells, yet both donor and host reactive Vβ subsets were deleted. These data not only showed that the HSC graft mediated negative selection of developing T cells, but additionally that the allografts eliminated potentially self-reactive post-thymic T cells of NOD origin in the periphery.

Replacement of susceptibility genes of the host

The cumulative experience on genetic predisposition to the predominant forms of autoimmunity, reinforced by the GWAS data, shows that activities of multiple, interactive susceptibility genes drive these diseases. Since many of these genes are expressed on hematolymphoid cells, another way in which allogeneic HCT can modify pathogenic immune responses is by “replacement” of these key regulatory genes in the hematopoietic compartment. MHC genes are the prototypic, and indeed the only, gene family identified to date that fit this description, and there are numerous examples that demonstrate that adding or replacing the MHC susceptibility allele by HCT, formal genetic crosses or transgenic technology provide disease protection [159,177]. That gene products outside the MHC can also halt autoimmune pathology has been demonstrated in preclinical models of MHC-matched HCT transplantations [4,131,136,191]. However, given that most preclinical studies demonstrating successful treatment of advanced ADs were performed with MHC-mismatched BM, there is some doubt whether similar consistent positive outcomes will be observed when AD-affected humans are transplanted with HLA-compatible grafts.

The GWAS analyses highlight the spectrum of non-MHC genes expressed in hematopoietic cells that can potentially alter the course of autoreactivity (selected genes shown in Table 18.3). These genes include those that affect overall immunoreactivity such as cytokines, cell proliferation, lymphocyte or APC cell activation, and apoptosis. For example, cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4), a hematopoietically expressed molecule and critical regulator of T-cell activation, has been identified as a major non-MHC susceptibility gene associated with ADs in humans and mice, including NOD diabetes [102]. The studies imply that common allelic variation in the expression of levels of alternative splice forms of CTLA-4 is a primary determinant of AD susceptibility.

An approach that we have taken in NOD mice to identify the non-MHC genes expressed on hematopoietic cells that confer protection in the setting of HCT is to use as donors congenic mice generated by recombinant inbreeding. Extensive efforts by several groups led to the generation of NOD mice that contain congenic intervals in their genome, termed *Idd*, derived from the C57BL strain [74,81]. Depending on the introduced chromosomal interval, these congenic NOD mice demonstrate different degrees of diabetes protection. Among the known *Idd* loci, the most protective non-MHC loci introduced map to chromosome 3 (*Idd3*), chromosome 1 (*Idd5*), and chromosome 4 (*Idd9*). Our earlier studies showed that HSC transplantation from MHC-matched B6.H-2^{g7} donors that express the full compliment of C57BL background provided 100% disease protection [136]. Therefore, to determine whether one or more of these congenic intervals contained a transferable protective gene(s), BM from NOD *Idd3*, *Idd5*, and/or *Idd9* congenic donors were transplanted into lethally irradiated prediabetic wild-type NODs. Mice that received grafts carrying one or two protective loci developed diabetes. These results were disappointing, particularly because the mouse CTLA-4 gene maps within the *Idd5* region [192]. However, significant diabetes protection was conferred when NOD mice that express multiple (*Idd3*, *Idd9*, *Idd10*, *Idd17*, and *Idd18*) protective alleles were used as donors. Hence our NOD congenic studies show that in this model of autoimmunity, protection by HCT depends upon multiple disease-resistant loci outside the MHC. Progress in the genetic basis of T1DM supports this finding, as several studies described interactions of CTLA-4 with other susceptibility loci that regulate expression and therefore contribute to the pathogenesis [192,193].

Regulatory cells

Despite the prominence of Tregs in the basic and clinical immunology literature, few reports exist on the role of regulatory T cells as a mechanism by which allogeneic HCT blocks autoimmunity; and studies to date do not show a definite role for regulatory cells as a major mechanism by which allografts control autoimmunity. We studied the potential contribution of Tregs to disease amelioration in NOD chimeras in two different types of experiments [136]: (1) by measuring the percentage and absolute numbers of Tregs ($CD4^+CD25^+$ cells) in the blood of control and transplanted mice, we observed that unmanipulated NOD mice had higher levels than MHC-matched disease-resistant B6.H-2^{g7} donors, and diabetes protected chimeras had levels equivalent to wild-type NODs, (2) B6.H-2^{g7} SCID mice lack both $CD4^+CD25^+FoxP3^+$ cells and another subset of regulatory T cells, NKT cells, were used as hematopoietic cell donors. Despite the inability of the donated cells to generate these T-cell subsets, NOD recipients enjoyed nearly 100% disease protection. In contrast to our negative results, Herrmann et al. [144] reported in a MOG-induced EAE rat model that increased levels of $CD4^+CD25^{bright}$ cells in lymph nodes and increased expression of Foxp3 in the spleens were observed in EAE-protected transplanted rats compared with untransplanted controls. However, similar to our studies, they found that the EAE-susceptible rat strain had higher levels of $CD4^+CD25^{bright}$ cells in their lymph nodes than disease-resistant rats. Given the known importance of Tregs in the control of immunity, these negative results should not deter testing of Tregs as adjunctive cellular therapy in HCT for autoimmunity, since it is clear that shifting the balance in this way towards tolerogenic outcomes is in line with “standard operating procedure” of the immune system.

Conclusion

The knowledge that autologous and allogeneic HCT cause profound alterations in immune reactivity resulting in cures of ADs has been present in the scientific and clinical literature for decades. The animal studies provide a fundamental basis for understanding both the potential benefits and limitations of HCT to treat these complex diseases effectively. The experimental details discussed in this chapter are meant to provide a foundation for the thoughtful translation of these studies into clinical reality.
